The term ''electrocatalysis'' denotes the catalysis of an electrochemical reaction. In accord with the general definition of catalysis[1] the effect of an electrocatalyst is to increase the rate of an electrochemical reaction without modifying the overall standard Gibbs energy change in the reaction. Taking the view of Faraday's law, the rate of an electrochemical reaction is expressed by the electrolytic current. Consequently, an increase in the electrolytic current is the main result of electrocatalysis. The benefits of electrocatalysis include making possible the quantitation of the catalyst itself or of some substrate compounds that are not electrochemically active or are not generally amenable to direct electrochemical determination. An appreciable improvement in selectivity may be brought about by electrocatalysis. Additionally, appropriate engineering of catalytic layers on electrode surfaces has led to the preparation of a huge variety of chemical and biochemical sensors. However, close control of the experimental conditions (temperature, electrolyte composition) is often required when dealing with electrocatalytic processes. Usually, such requirements do not give rise to any particular difficulties.

1 INTRODUCTION

In contrast to conventional chemical reactions, the activation energy of an electrochemical reaction depends not only on the molecular/chemical factors (included in the so-called thermal term) but also on the electrode potential. That is why the rate constants for electrochemical reactions are exponential functions of the electrode potential. For the most simple electrochemical reaction (Equation 1)

$$\mathrm{Ox} + \mathrm{e} \rightleftharpoons \mathrm{Red} \tag{1}$$

the current–potential relationship is expressed by the Butler–Volmer relationship (Equation 2):[2]

$$i = i_0 \left\{ \exp\left(\frac{-\alpha F \eta}{RT} \right) - \exp\left(\frac{(1-\alpha) F \eta}{RT} \right) \right\} \tag{2}$$

where i_0 is the exchange current, α is the transfer coefficient ($\alpha \leq 1$), F is the Faraday constant, T is the absolute temperature and R is the gas constant. η denotes the overvoltage, i.e. the deviation of the actual electrode potential E from the equilibrium value E_e (Equation 3):

$$\eta = E - E_e \tag{3}$$

The expression for the exchange current (Equation 4) includes the standard rate constant for the electrode reaction, k_s

$$i_0 = FAk_s c_{\mathrm{Ox}}^{(1-\alpha)} c_{\mathrm{Red}}^{\alpha} \tag{4}$$

where A is electrode area, and c_{Ox}, and c_{Red} stand for the bulk (equilibrium) concentrations. According to Equation (2), the absolute value of the current rises exponentially with the increase in the absolute value of the overvoltage. In practise, a nonelectrochemical step always limits the current increase to a value that is termed the limiting current. Under such circumstances, the rate-determining step can be either the transport of the reactant towards the electrode surface or a chemical reaction producing the electrochemically active species. In the last case, the term ''kinetic current'' is used to denote this special type of limiting current.

The effect of electrocatalysis is an increase in the standard rate constant, k_s, which is followed by a rise in current value at a constant overvoltage. Because this effect can be masked by the intervention of a nonelectrochemical rate-determining step, the most straightforward mark of electrocatalysis is the shift of the electrode process to a lower overvoltage (in absolute value).

An electrochemical reaction, involving the electron transfer between two different phases, is intrinsically a heterogeneous process. However, electrocatalysis can be either heterogeneous or homogeneous in character. In the first case, the catalyst is confined to the electrode surface by adsorption, chemical bonding, adhesion or some other immobilization procedure. In the second case, the catalyst is present in the bulk of the solution and interface processes do not influence the chemical steps that involve it. A much more detailed approach of the general theory of electrocatalysis is available in the literature, with emphasis on technological applications.[2,3] Some monographs on kinetic methods of analysis also include sections on electrocatalysis applications in electroanalytical chemistry.[4,5] This topic is periodically surveyed in reviews published by the Journal *Analytical Chemistry*, jointly with either *Kinetic Methods of Analysis* or *Electroanalytical Chemistry*.

2 ELECTROCATALYSIS AT BARE ELECTRODES

A characteristic feature of bare-electrode processes is the occurrence of both the catalyst and the substrate in the bulk solution. Consequently, the process involves mass transfer processes for both. According to the nature of the catalyst-involving step, three kinds of electrocatalytic processes at bare electrodes can be distinguished: redox-type catalytic processes (mediated electron transfer), processes with proton transfer as a regenerative step (catalytic hydrogen evolution), and processes with a complex-forming regenerative step (catalytic reduction of some metal ions). Most of the research in this field has been done with mercury electrodes using either polarography or voltammetry at a stationary electrode, which is why the following discussion relates mostly to reduction-based processes. However, the conclusions can be easily transposed to anodic reactions.

2.1 Redox-type Catalytic Processes

2.1.1 Reaction Mechanism and Theoretical Approach

A general reaction scheme for redox-type catalytic processes can be formulated as Equations (5–8), shown in Scheme 1.

$$P + e \rightleftharpoons Q \quad (5)$$

$$Q + A \underset{k_2}{\overset{k_1}{\rightleftharpoons}} B + P \quad (6)$$

$$B \xrightarrow{k} C \quad (7)$$

$$A + e \rightleftharpoons B \quad (8)$$

Scheme 1

The couple P/Q plays here the role of an electron carrier from the electrode to the substrate A via Equations (5) and (6). The term ''mediator'' is frequently used to denote the couple P/Q or one of its members. Equation (6) represents the regeneration step involving the substrate A, leading to the reformation of the direct electron acceptor, P. In principle, the direct electrochemical conversion of the substrate (Equation 8) is also possible. However, a prerequisite for the catalytic process is the occurrence of this reaction at a more negative potential than that of Equation (5). The couple A/B must be a more powerful oxidant than P/Q (i.e. $E^0_{A/B} > E^0_{P/Q}$), but Equation (8) occurs with a high activation energy (i.e. high overvoltage) and is shifted to potentials much more negative than its standard potential. The electrolytic current for the above mechanism is known as the catalytic current. The term ''parallel reaction'' is often used for Equation (6), with Equation (5) being the main step. An electrochemical reaction with a parallel chemical regeneration (EC′) is distinct from an electrochemical reaction with a subsequent chemical reaction (EC; i.e. with no regeneration). The subscripts ''r'' or ''ir'' attached to either E or C indicate the reversible or irreversible character of Equations (5) and (6), respectively. From the kinetic standpoint, the reversible or nernstian behavior of Equation (5) is defined by the condition $k_s \rightarrow \infty$ (where k_s is the standard rate constant for Equation 5) whereas an irreversible character corresponds to a low value of k_s. In thermodynamic terms, the nernstian character of

the reaction means that the Nernst equation relative to interface concentrations of both P and Q is fulfilled. The occurrence of Equation (7) is usually neglected.

A typical example of a redox-type catalyzed process is the reduction of Fe^{3+} in the presence of hydrogen peroxide[6,7] (Figure 1). In this case, the substrate is H_2O_2, whereas the couple Fe^{3+}/Fe^{2+} plays the role of the electron carrier, P/Q, according to Equations (9) and (10):

$$Fe^{3+} + e \rightleftharpoons Fe^{2+} \quad (9)$$

$$2Fe^{2+} + H_2O_2 + 2H^+ \longrightarrow Fe^{3+} + 2H_2O \quad (10)$$

The main analytical application of this kind of electrode process is the analytical determination of P with an enhanced sensitivity due to the regeneration step (Equation 6). Accordingly, an increase in the reduction current of P occurs at the expense of the substrate A.

The theoretical approach aims at establishing the relationship between the limiting current on one side and the rate constant and reactant concentrations on the other side. A time parameter is always included in the kinetic equation, because of the dynamic character of the electrode process.

Most of the available theoretical treatments assume that the substrate is present in a high excess as compared with the mediator (so that Equation 6 is pseudomonomolecular) and Q is not initially present in the solution. Substrate excess is favorable from the standpoint of the analytical determination of P because maximum sensitivity is thus achieved. In addition, it is assumed that Equation (6) occurs by outer-sphere electron transfer and, consequently, does not involve the formation of an intermediate adduct. Adsorption of the compounds involved in the electrode process brings about some complications and is usually neglected. Under these circumstances Equation (6) occurs in a solution layer (the reaction layer) adjacent to the electrode surface. Under such ideal conditions, the regeneration step is a homogeneous reaction, with no effects from the electrode–solution interface. Equation (7) is assumed to be very fast and to have no kinetic relevance. These assumptions should be carefully considered when doing kinetic investigations, but are generally not critical from the standpoint of analytical applications.

Figure 1 Direct current (DC) polarograms showing the catalytic effect of the Fe^{3+}/Fe^{2+} couple on the electrochemical reduction of hydrogen peroxide. Background electrolyte: 0.1 M KOH, 4×10^{-2} M triethanolamine. Curve 1 shows the reduction wave of Fe^{3+} (1×10^{-6} M) in the absence of H_2O_2 (Equation 9). Curves 2–5 show the electrochemical processes in the presence of both Fe^{3+} (1×10^{-6} M) and H_2O_2 (1.5×10^{-4} M) for the following values of the mercury column height, h (in cm): (1 and 2) 90; (3) 75; (4) 60; (5) 45. All polarograms start at −0.8 V vs SCE (saturated calomel electrode). A comparison of the first wave on curve 2 with the wave on the curve 1 demonstrates the increase in the limiting current due to Equation (10). The limiting current of this wave is independent of h (curves 2–5). This proves that Equation (10) (and not mass transfer processes) is the rate-determining step. The second wave on curves 2–5 is due to the diffusion-controlled reduction of H_2O_2 (Equation 8 in Scheme 1).

Theoretical treatments for the above mechanism have been developed for various electrochemical methods and are amply reviewed.[6–13] The following discussion is confined to electrochemical methods currently used in chemical analysis. However, such methods also provide valuable tools for the kinetic investigation of any chemical reaction that may occur as a regeneration step in a catalytic electrode process. In addition, this kind of investigation can provide useful information for selecting an appropriate mediator when developing chemically modified electrodes (CMEs) with electrocatalytic properties (sections 3 and 4).

Generally, two kinds of theoretical approach may be used when dealing with any class of electrode process coupled with chemical reactions.[6–9] The rigorous approach proceeds by solving the mass-transfer differential equations that include some additional terms corresponding to the formation or elimination of the reactants (e.g. P, Q, and A) by the chemical reactions. For simplicity, it is often assumed that the diffusion coefficients have the same value for all the species involved. Although only numerical solutions for such equations are available, under limiting conditions it is still possible to obtain an analytical expression for the current as a function of the rate constant, reactant concentrations, and a time-parameter characteristic for each particular electrochemical method.

The more simple, but approximate, approach is based on the concept of the reaction layer. This is the solution layer adjacent to the electrode surface, where the equilibrium of Equation (6) is disturbed by the occurrence of Equation (5). If the regeneration rate is very fast, the diffusion of P may be neglected and the single species taking part in the diffusion process is A. Furthermore, it is assumed that the thickness of the reaction layer is very small compared to the thickness of the diffusion layer for A. Consequently the concentration of A inside the reaction layer is assumed to be constant. In addition,

it is supposed that the steady state occurs within the reaction layer, i.e. the formation of P by Equation (6) is completely balanced by its removal via Equation (5). Hence, the reaction layer method is restricted to the limiting case of a very fast parallel chemical reaction.

An alternative to the above methods is the digital simulation of the electrode process.[14] The mass transfer model is discretized into events that occur within small time increments and small intervals of distance from the electrode surface. In this way, the concentration versus distance profiles can be calculated by successive iterations. Initial assumptions about the mechanism and the rate parameters must be made, and this makes unavoidable the use of the diagnostic criteria and relevant relationships derived by the previous methods. However, digital simulation is very useful when checking the validity of some approximations or for investigating complicated processes that cannot be handled by solving the relevant set of differential equations.

2.1.2 Kinetic Equations

2.1.2.1 Direct Current Polarography Most of the pioneering work in the field of catalytic electrode processes was done by the Czech school of polarography and is amply reviewed elsewhere.[6–8,11–13] As a rule, the effect of sphericity is neglected and the dropping mercury electrode is regarded as an expanding plane electrode. This common approximation is valid provided that the thickness of the diffusion layer is much smaller than the electrode radius.

Taking into account the restrictions mentioned in the previous section, the solution to the system of differential equations for the diffusion of P and Q, accompanied by the irreversible pseudo-first-order Equation (6), is expressed by Equation (11):[6]

$$\frac{i_c}{i_d} = \Psi(\chi_1) \tag{11}$$

Here, i_c is the mean limiting catalytic current and i_d is the mean diffusion current of P (which can be measured in the absence of the substrate A). The dimensionless parameter χ_1 is defined in Equation (12):

$$\chi_1 = k_1 c_A^0 t_1 \tag{12}$$

where c_A^0 is the concentration of the substrate and t_1 is the drop time for the dropping mercury electrode. The ratio i_c/i_d represents the current amplification brought about by the regeneration step. A high regeneration rate, due for example to a high excess of substrate ($\chi_1 > 10$), has a beneficial effect on the sensitivity. Under these conditions, the amplification factor is given by the following asymptotic form (Equation 13):

$$\frac{i_c}{i_d} = 0.81(k_1 c_A^0 t_1)^{1/2} \tag{13}$$

The above treatment is applicable only to the limiting-current region, i.e. for potential values negative enough to make the charge transfer reaction (Equation 5) very fast and kinetically irrelevant. An approximate expression for the current–voltage curve, which is valid for any potential value on the kinetic wave, is also available.[15] Accordingly, the catalytic wave is described by the well-known equation of the polarographic wave (Equation 14):

$$i = \frac{i_c}{1 + \exp[\alpha n F(E - E_{1/2})/RT]} \tag{14}$$

where i is the current as a function of electrode potential E, n is the stoichiometric coefficient of the electron in the electrode reaction (Equation 5) and $E_{1/2}$ is the half-wave potential. For the case of a reversible electrode reaction $E_{1/2} = E_{P/Q}^0$ and $\alpha = 1$. For the opposite case of an irreversible electrode reaction, under the limiting conditions of a very fast parallel reaction ($\chi_1 > 10$), $E_{1/2}$ is dependent on both k_s and the rate constant k_1 (Equation 15):

$$E_{1/2} = E^0 + \left(\frac{RT}{\alpha n F}\right) \ln \frac{k_s}{(D_P k_1 c_A^0)^{1/2}} \tag{15}$$

where D_P is the diffusion coefficient of P. The above relationships appear as particular cases of a more general treatment which is not restricted to the steady-state assumption and refers to an electrode expanding with any power law.[16] Because most of the available theoretical treatments deal with the expanding plane electrode, the effect of electrode sphericity has been assessed[17] and it was concluded that i_c is more affected than $E_{1/2}$ by this approximation; however, only slight corrections are required.

If the regeneration step (Equation 6) is a second-order reaction, a subunitary correction factor should be added to Equation (13).[6] This obviously brings about a decrease in the sensitivity of the determination of P.

DC polarography provides some straightforward diagnostic tests for the occurrence of the catalytic electrode process. The most typical case is that corresponding to Equation (13). This implies a very fast regeneration of P and no concentration gradients for A (which is present in a high excess) or P and Q (which are cycled inside the reaction layer). Consequently, the overall electrode process is independent of mass-transport phenomena.[6] Experimentally this is proved by the independence of the limiting catalytic current, i_c, on the mercury pressure above the mercury electrode (expressed by the height of the mercury level above the lower end of the capillary

electrode, h) (Figure 1). This contrasts the behavior of the diffusion current, which is directly proportional to $h^{1/2}$. Under intermediate conditions, the i_c versus $h^{1/2}$ plot gives a straight line with a nonzero intercept. The investigation of the deuterium isotope effect is a valuable test for detecting the participation of hydrogen species in the rate-determining chemical step.[18]

2.1.2.2 Linear Sweep Voltammetry and Cyclic Voltammetry at Stationary Electrodes Linear sweep voltammetry (LSV) is an essentially nonsteady-state method under convection-free conditions, involving a potential scan according to Equation (16):

$$E = E_i + vt \tag{16}$$

where E_i is the initial potential, v is the scan rate (in $V\,s^{-1}$), and t is the time variable. The output is the current–potential curve (known as a voltammogram) which displays asymmetric peaks corresponding to each electrode reaction. Cyclic voltammetry (CV) involves potential cycling with constant speed between two potential values. This makes it possible to detect the product of the initial scan from the relevant peak recorded during the reverse process.

The theory of the catalytic process in LSV, as worked out by Savéant and Vianello[19] and Nicholson and Shain,[20] is amply described elsewhere.[11–13] It is assumed that $c_A^0 \gg c_p^0$ and $k_2 = 0$, so that Equation (6) is pseudomonomolecular and irreversible. The perturbation of the system is expressed by the dimensionless sweep rate $a = nFv/RT$, whereas the mobility of the chemical reaction is shown by the pseudomonomolecular rate constant $k_1 c_A^0$. The treatment assumes a planar electrode (i.e. semi-infinite planar diffusion) but the results are reasonably correct for spherical electrodes as well. This is because the relevant processes occur in the reaction layer, which has a thickness much lower than the electrode radius.

The general solution of the differential equations for the mass transfer accompanied by the chemical reaction gives the current–potential relationship in the form of a series. First, the case of the reversible electrode reaction is considered (i.e. $E = E_{P/Q}^0 + (RT/nF)\ln(c_{P,i}/c_{Q,i})$; the subscript i denotes concentrations at the electrode/solution interface). If the regeneration is very fast ($k_1 c_A^0/a \gg 1$), the current–potential curve assumes the shape of the steady-state voltammetric wave and is described by Equation (14) where $\alpha = 1$ and $E_{1/2}$ is the polarographic half-wave potential for the electron transfer reaction (Equation 5) (i.e. $E_{1/2} = E_{P/Q}^0 - (RT/2nF)\ln(D_P/D_Q)$; usually, $E_{1/2} \approx E_{P/Q}^0$ because $D_P \approx D_Q$). Under these conditions, the value of i_c is dictated by the rate of the parallel reaction, according to Equation (17):

$$i_c = nFAc_P^0(D_P k_1 c_A^0)^{1/2} \tag{17}$$

Accordingly, i_c is not dependent on the scan speed, in contrast with the peak current for the diffusion-controlled process, i_p, which is recorded in the absence of A and is directly proportional to $v^{1/2}$. This is an important diagnostic test for the catalytic process, in addition to the curve shape and the absence of the hysteresis on a CV run (provided that the reversal potential is not more negative than $(E_{1/2} + 35/n)$ mV). Equation (17) enables a straightforward determination of the rate constant k_1.

The current amplification brought about by the regeneration of the electron acceptor is defined in Equation (18):

$$\frac{i_c}{i_d} = 2.242(k_1 c_A^0)^{1/2} a^{-1/2} \tag{18}$$

At a very high scan speed ($k_1 c_A^0/a \ll 1$) the effect of the regeneration becomes less evident and the shape of the voltammetric pattern becomes an asymmetric peak. At the limit, the timescale is so short that Equation (6) is not disturbed any longer and the rate-determining step is the diffusion of P.

If Equation (6) is reversible, both k_1 and k_2 must be taken into account and the limiting current recorded at a low sweep rate ($k_1 c_A^0/a \gg 1$) is given by Equation (19):[11,21]

$$i_c = nFAc_P^0[D_P(k_1 c_A^0 + k_2)]^{1/2} \tag{19}$$

In the case of the irreversible electrode reaction the rate of Equation (5) is expressed by the Butler–Volmer equation and the dimensionless sweep rate is defined as $b = \alpha nFv/RT$. The current–voltage relationship is available as a series.[11,20] However, for the analytically important case of a very fast regeneration ($k_1 c_A^0/b \gg 1$), the current–voltage relationship is in accord with Equation (14), i.e. it has a sigmoid shape with a limiting current i_c as given by Equation (17). The effect of irreversibility is demonstrated by the shape of the curve, which is more spread out than in the case of the reversible reaction (because $\alpha < 1$), and by the dependence of $E_{1/2}$ on the rate constants for Equations (5) and (6).

The LSV technique has limited analytical applications but it is a very valuable tool for investigating catalytic electrode processes of analytical interest, involving either synthetic or biogenic catalysts.

2.1.2.3 Differential Pulse Polarography, Square-wave Voltammetry, and Alternating Current Polarography The above methods are characterized by the superposition of a periodic, small amplitude voltage (10–100 mV)

over the constant polarization potential. The superimposed signal is either square shaped (for differential pulse polarography (DPP) and square-wave voltammetry (SWV)) or is a sine wave (for alternating current (AC) polarography). An outstanding sensitivity is achieved owing to the ability of such methods to distinguish the electrolytic current (which bears the analytical information) from the disturbing capacity current. Additional improvement in the sensitivity and the detection limit is brought about by coupling the electrode reaction (Equation 5) with the chemical regeneration step (Equation 6).

In the case of DPP[11,22] an amplification factor of $(\tau\pi k_1 c_A^0)^{1/2}$ results from the theoretical analysis of the $E_rC'_{ir}$ process for the most favorable case of a very fast regeneration (where τ is the pulse duration). A treatment for the more general case, involving stoichiometric factors other than unity in Equations (5) and (6), is also available.[23]

The most successful version of the square-wave methods is SWV, which involves a fast variation of the polarization potential (typically, $10\,V\,s^{-1}$), thus combining a high sensitivity with a very short duration of the run. The theoretical treatment for the $E_rC'_{ir}$ mechanism shows that in the purely kinetic region ($k_1 c_A^0 p > 2$; p is the square-wave period) the response (known as the net current, i.e. the difference between current values sampled at the extremes of the square wave pulse) is proportional to $(k_1 c_A^0 p)^{1/2}$ and c_P^0.[24] The modulation frequency has no effect on the current, but the lowest possible (e.g. 10 Hz) is recommended because this leads to a very low capacity current. An outstanding detection limit (2.5×10^{-8} M) for Ti^{IV} determination by catalytic SWV in the presence of ClO_3^- as a substrate was reported.[25]

AC polarography has not enjoyed so much attention as the other methods, although the theoretical treatment performed for the $E_rC'_{ir}$ mechanism, assuming planar diffusion at a constant-area electrode, demonstrates the same kind of favorable effect of the parallel reaction (as pointed out before). In the most favorable case of a very high reaction rate ($k_1 c_A^0 \gg w$; w is the angular frequency of the modulating sine wave) an increase in the peak current by a factor of $(k_1 c_A^0 / w)^{1/2}$ is predicted, compared with the diffusion current of P (i.e. the peak current recorded for $k_1 c_A^0 = 0$).[11,26] Under the above assumption, the peak current is not dependent on w, because of the fast regeneration of P, but it is directly proportional to $(k_1 c_A^0 D_P)^{1/2}$ and c_P^0. A comprehensive review of the theory for AC methods including catalytic electrode reactions provides more details.[9]

2.1.2.4 Hydrodynamic Voltammetry The methods included in this class involve electrolysis under controlled and reproducible electrolyte flow conditions. Consequently, the mass-transfer process to the electrode fulfills the conditions for the steady state. Among the systems in this class, the most common are rotating disc, wall-jet, and the flow-through (tubular or channel) electrodes.[27] The latter types are applicable to continuous analytical measurement.

A general solution for the rotating disc electrode (RDE) is available in the case of the $E_rC'_{ir}$ mechanism (Equation 20):[11,27]

$$\frac{i_c}{i_d} = x\,\mathrm{cotanh}(x) \tag{20}$$

where $x = 1.61(\nu/D_P)^{1/6}(k_1 c_A^0/w)^{1/2}$, ν is the cinematic viscosity, and w is the angular velocity of the rotating disc. For a very fast regeneration the current amplification is $i_c/i_d = x$.[11,27] Under the same conditions, i_c is proportional to c_A^0 (via i_d) and is not dependent on w.

The theory for the EC′ mechanism at a channel electrode[28] gives the (i_c/i_d) ratio as a function of a dimensionless kinetic parameter including the rate constant k_1 and the electrolyte flow rate. The solution is available both as a series and as working curves. A number of variations in the EC′ mechanism occurring at a channel electrode were recently examined by numerical computation.[29] For the most simple case of an $E_rC'_{ir}$ mechanism, the current–voltage curves have the typical shape for a steady-state process, in agreement with Equation (14) with $\alpha = 1$. Although the solutions are more complicated than for the RDE, it is still clear that the amplification factor increases with an increase in both k_1 and c_A^0.

2.1.2.5 Adsorption Effects Adsorption at the electrode interface is a common feature in electrochemistry of organic compounds or complexes containing organic ligands. It brings about a series of theoretical complications that originate in the deviation from the equilibrium state of the adsorption process or in the effect of electrode potential on the parameters of the adsorption isotherm. However, the adsorption of one or more participants in the catalytic process may favorably enhance the overall reaction rate as a consequence of the augmented local concentrations. Special advantages were demonstrated in the case of adsorptive stripping voltammetry (ASV) where the adsorption represents the basis for the preconcentration step.

A theoretical treatment for heterogeneous redox catalysis was performed under the assumption that the mediator couple is confined to the electrode surface as a monomolecular layer, either by irreversible adsorption or by another method of electrode modification.

When dealing with the CV of a nernstian system ($E_rC'_{ir}$) the dimensionless kinetic parameter was defined as in

Equation (21):[30]

$$\Lambda_s = k_1 \Gamma_T \left(\frac{RT}{FvD_A} \right)^{1/2} \quad (21)$$

where Γ_T is overall surface coverage ($\Gamma_T = \Gamma_P + \Gamma_Q$). The overall current is the algebraic sum of the current produced by Equation (5) alone (i_s) and the purely kinetic component brought about by the occurrence of Equation (6) in the adsorbed state, i_c. The effects of Equation (6) on the peak current and potential are available in a graphical form, as a function of both Λ_s and the departure from $E^0_{P/Q}$.[30] With the increase in Λ_s, the i_c versus E curve changes in shape, from a sigmoid hysteresis-free curve to an asymmetrical peak. Simultaneously, the overall process turns from a kinetically controlled one (for small Λ_s values) to control by the diffusion of A when $\Lambda_s \to \infty$. This change is accompanied by a strong increase in i_c and the shift of half-peak potential towards more negative values. The limiting value of i_c still cannot overcome the diffusion-controlled current of A at a bare electrode. Such conditions are suitable for the determination of the substrate.

If Equation (5), occurring in the adsorbed state, is followed by the formation of an adsorbed Q–A complex, an intramolecular electron transfer proceeds as Equation (6) and the product decomposes, leading subsequently to the regeneration of P.[31] Assuming that the complex formation is at equilibrium and that Equation (5) is reversible, the relevant kinetic parameter Θ was defined as in Equation (22):

$$\Theta = k_3 K_{QA} \Gamma_T \left(\frac{RT}{FvD_A} \right)^{1/2} \quad (22)$$

where k_3 is the rate constant for the intramolecular electron transfer, K_{QA} is the equilibrium constant for complex formation and $\Gamma_T = \Gamma_P + \Gamma_Q + \Gamma_{QA}$. At a small, fixed value of $K_{QA}c^0_A$ ($K_{QA}c^0_A \leq 0.1$), an increase in Θ from 0.1 to 30 makes the peak current i_c increase towards a limit which corresponds to kinetic control by the diffusion of A. Simultaneously, the shape of the i_c–E curve changes from sigmoid (which is characteristic of the absence of a noticeable concentration gradient of A) to the usual, peak-shaped form of the voltammogram. At the same time, the peak potential, which is dictated by the P : Q concentration ratio in the adsorbed state, shifts towards more positive values. At a constant and small value of Θ (kinetic control), the increase in $K_{QA}c^0_A$ induces a decline in i_c with no marked change in the peak potential. The effect of $K_{QA}c^0_A$ is much less marked for $\Theta > 10$.

The above results also provide an interpretation of electrocatalysis at modified electrodes. With the bare electrode, at least some qualitative insight into heterogeneous catalysis can be drawn. For example, the above conclusion can be used for interpretation of the processes occurring in the quantitative determination of the catalyst by stripping voltammetry with adsorptive preconcentration. Under such circumstances, the presence of the catalyst in the bulk solution (usually, under 10^{-7} M) can be neglected and the catalytic effect is due to the adsorbed species only. In this case, one major deviation from the above treatments may be the reversible character of catalyst adsorption, leading to gradual desorption during the potential scan.

2.1.2.6 Electrocatalysis at Ultramicroelectrodes The use of the UME (ultramicroelectrode), defined as an electrode with the characteristic dimension of 1 μm or less,[32] shows a series of advantages: small interference arising from capacity current and electrolyte resistance, allowing the use of highly resistive media including nonpolar solvents; the possibility of approaching steady-state mass transfer without convection; and suitability to microscale and in vivo analysis. Various UME shapes are disc, ring, disc array, hemisphere, band, cylinder and interdigitated array.

A particular feature of the UME is that the steady-state mass transfer occurs even in the absence of the convection, provided that the characteristic dimension (e.g. sphere radius r_s) is much lower than the thickness of the diffusion layer ($r_s \ll (D\tau)^{1/2}$, where τ is the timescale of the experiment, such as the pulse duration in DPP or duration of potential scan in LSV).[33] Accordingly, a more general definition of the UME is proposed by Amatore[34] who assumes that any electrode/electrolyte system shows the behavior of the UME if $r_s \ll \delta$, where δ is the thickness of the convection-free solution layer at the electrode surface. The factor δ depends not only on D and τ but also on the hydrodynamic conditions and electrolyte viscosity. Under such conditions, radial (convergent) diffusion prevails over planar diffusion. Rather than the dimension itself, the occurrence of radial diffusion is the main characteristic of a UME. In principle, this definition does not impose an upper limitation in the electrode dimension. However, it must be stressed that the advantages emerging from the small-capacity current and very small ohmic voltage drop arise only if the electrode dimension is under 100 μm.

The use of the UME for kinetic investigations has been reviewed by Montenegro.[33] Under steady-state conditions, the diffusion-controlled reduction of the P species (Equation 5 alone) gives a sigmoid i–E curve (in accord with Equation 14) with a plateau corresponding to the limiting diffusion current i_d. The occurrence of the $E_rC'_{ir}$ mechanism (with pseudo-first-order regeneration) induces a higher plateau current (i_c), according to

Equation (23):[35]

$$\frac{i_c}{i_d} = 1 + \Lambda_m^{1/2} \tag{23}$$

with i_d as in Equation (24):

$$i_d = \frac{FADc_P^0}{r_s} \tag{24}$$

The dimensionless kinetic parameter Λ_m is defined in Equation (25):

$$\Lambda_m = \frac{r_s^2 c_A^0 k_1}{D} \tag{25}$$

Here, r_s is the radius for a hemispherical electrode (e.g. a mercury hemisphere electrolytically deposed on a Pt microdisc). The rate constant k_1 can be determined from the slopes of the i_c/i_d ratio versus r_s plot (at constant c_A^0) or i_c/i_d ratio versus $(c_A^0)^{1/2}$ plot (at constant r_s). Alternatively, the above equations are easily rearranged aiming at data analysis by means of the i_c versus $1/r_s$ plot.[36] The pseudo-first-order conditions are fulfilled if $c_A^0 \gg k_1 r_s^2 c_P^2/D$.[37] However, the occurrence of the steady state is favored by a high Λ_m/q ratio, where q is the dimensionless potential sweep rate ($q = (Fvr_s^2/RTD)^{1/2}$).[35] Empirically, the occurrence of the steady state can be demonstrated by the independence of i_c on v or by performing a logarithmic plot of the curve according to Equation (14). A more general treatment for the catalytic mechanism at a hemispherical electrode with application to chronoamperometry, cyclic staircase voltammetry, and cyclic LSV was published recently.[38]

In the case of a second-order regeneration, the solution of the relevant differential equations for a spherical electrode leads to Equation (26) (under the assumption of equal diffusion coefficients for all the species involved):[39]

$$\frac{i_c}{i_d} = 1 - \left(\frac{k_1 r_s^2 c_P^0}{2D} + 0.5\left(\frac{k_1 r_s^2 c_P^0}{D}\right)^2 + (4\Lambda_m)\right)^{1/2} \tag{26}$$

In contrast to the pseudo-first-order reaction, the relationship between the i_c/i_d ratio and r_s is nonlinear in this case. Interestingly, the pseudo-first-order kinetic regime appears as a limiting case of the second-order one if $c_A^0 \gg k_1 r_s^2 (c_P^0)^2/D$. In other words, for small values of $k_1 r_s^2$ the process may assume pseudo-first-order character even if c_A^0 is close to c_P^0. Under these conditions, A is not depleted in the reaction layer and the A/P concentration ratio is very high here. Consequently, Equation (26) assumes the simple form of Equation (23).

The disc electrode (with radius r_d) was approached initially by asserting that it behaves like a hemisphere with an equivalent area and it is, therefore, sufficient to substitute r_s by $\pi r_d/4$ in the relevant equations for the hemispherical electrode. It was shown later that this is a very rough approximation in the case of the catalytic process and rigorous equations were derived accordingly.[40]

The effect of the difference between the diffusion coefficients was investigated by using the reaction layer concept.[41] Kinetic equations were derived under such conditions for either the first- or second-order homogeneous catalytic reaction at an ultramicrodisc electrode. In accord with the results for the spherical UME presented above, the reaction order can be controlled by changing the dimension of the UME. Thus, the second-order reaction can be changed to quasi-first-order by decreasing the dimension of the UME.[42]

It was stated that the microcylinder electrode shows important advantages from the standpoint of both theory and experiment. The theory of the EC'_{ir} mechanism with a second-order parallel reaction was worked out using the concept of the reaction layer and was applied to the Fe^{III}–ethylenediamine tetraacetic acid (EDTA)–H_2O_2 system.[43]

Although the steady state seems to be typical of the UME, the nonsteady state may also be attained. This occurs for a very low timescale ($r_d \gg (D\tau)^{1/2}$) and involves the planar diffusion. Under such conditions, the experimental data can be dealt with in the classical way (sections 2.1.2.2 and 2.1.2.3), with the advantage of a very low τ value, which allows the investigation of very fast electrode reactions.

2.1.2.7 Intramolecular Electron Transfer as a Regeneration Step As shown before, most of the available theoretical treatments of catalytic electrode reactions assume that the parallel chemical reaction proceeds via an outer sphere mechanism. Nevertheless, the occurrence of the opposite mechanism, involving a catalyst–substrate adduct, cannot be ruled out as was mentioned in section 2.1.2.5. The formation of a substrate–catalyst complex may occur, for example, in the case of some processes involving oxo cations as catalysts and hydrogen peroxide as the substrate.[44] This kind of mechanism is easily detected in DC polarography by the direct proportionality relationship between the i_d/i_c ratio and $1/c_A^0$.[45] The catalytic limiting current is directly proportional to substrate concentration under pseudo-first-order conditions and for $c_A^0 \gg K_{QA}$. Such conditions are appropriate for the substrate determination with a sensitivity that is directly proportional to the concentration of the catalyst.

2.1.3 Some Examples of Parallel Electrocatalytic Systems

Many early investigations were performed by DC polarography and a detailed compilation of the results

is available.[44] Data included in this review could provide useful information for developing analytical methods based on more advanced electroanalytical techniques.

Commonly, inorganic oxidants are used as substrates, including either neutral (hydrogen peroxide, hydroxylamine) or anionic species (chlorite, chlorate, perchlorate, bromate, iodate, nitrate, nitrite, persulfate ions). The mediator may be, in principle, any transition metal which shows two stable oxidation states. Metals in groups Ib (Cu), IVb (Ti^{IV}), Vb (V^{V}), VIb (Cr^{III}, Mo^{VI}, W^{VI}), VIII (Fe^{III}, Co^{III}, Ru^{III}, Os^{VIII}) as well as some lanthanides (Y^{III}) and actinides (U^{VI}) can be mentioned in this connection and appropriate methods for the polarographic determination of such metal ions were quoted.[44] An organic mediator (4-hydroxy-2,2,6,6-tetramethyl-piperidinyloxy radical) which catalyzes the anodic oxidation of hydrazine on a carbon electrode was also reported.[46]

Although Scheme 1 may accurately describe many real systems, frequent deviations occur due, for example, to the simultaneous occurrence of different chemical states of the catalyst, double-layer effects on reactions involving charged particles, and adsorption of complexes with organic ligands. A careful empirical optimization of the experimental parameters still allows the use of complicated processes for analytical purposes, even if the rigorous kinetic investigation is not possible.

Because the substrate is very often a covalent compound, Equation (6) may consist of several steps involving free-radical species. For example, in the $Fe^{III}/Fe^{II}-H_2O_2$ system this reaction occurs as shown in Equations (27) and (28):[6,8]

$$Fe^{2+} + H_2O_2 \longrightarrow Fe^{3+} + OH^- + OH\bullet \qquad (27)$$

$$Fe^{2+} + OH\bullet \longrightarrow Fe^{3+} + OH^- \qquad (28)$$

Analogously, hydroxylamine reduction by either Fe^{2+} or Ti^{III} involves $NH_2\bullet$ or $OH\bullet$ radicals.[6,8]

In the presence of a radical scavenger, such as ethanol or an organic ligand in excess, the stoichiometry of the regeneration step will change. Accordingly, the stoichiometric factor of Equation (5) should be included in the kinetic equation as a multiplier for k_1. This factor indicates how many times Equation (5) occurs for each occurrence of Equation (6), i.e. it is the ratio of the stoichiometric coefficients of Q in Equations (6) and (5). Thus, for the $Fe^{3+}-H_2O_2$ system (Equations 9 and 10), the stoichiometric factor is two but it decreases towards one in the presence of ethanol. Consequently, the presence of radical scavengers will produce a drop in sensitivity. Detailed investigations on this topic have been made with special reference to LSV.[19]

Hydrogen peroxide is by far the most widely applicable substrate and many of the above-mentioned mediators react with it giving catalytic currents for potential analytical applications. Some particular features are the effect of pH on H_2O_2 oxidizing power and the formation of peroxo complexes of various catalyst ions (Ti, V, Mo, W, Nb, Hf, Zr, Ta) followed by a shift in the redox potential of the metal ion to less negative values.

Hydroxylamine also shows a broad area of applications (for Nb, Ru, and W). Chlorate and bromate ions are also strong oxidants with many possible applications, but the negative charge may lead to intricate polarographic shapes, especially when the mediator itself is an anion, such as Mo^{VI} or W^{VI}. Worthy of mention is the catalytic current of selenium (after reduction from SeO_3^{2-} to H_2Se and redox cycling between this state and Se^0) in the presence of BrO_3^-. Perchlorate ion is a milder oxidant and only Mo^{VI} and W^{VI} give catalytic currents in its presence. The catalytic activity of Mo^{VI} and W^{VI} is depressed by complex formation. Iodate and periodate provide catalytic currents for organic sulfur compounds, such as for the cystine/cysteine couple.

2.1.4 Analytical Applications

Redox-type electrocatalytic processes can be used to determine the catalyst, the substrate, an activator or an inhibitor of the redox reaction; the first of these applications is most usual. Substrate determination may be more conveniently done by electrocatalysis at a modified electrode (section 3), although the advantages of bare electrodes (readily available, reproducible response and a broad field of application) can very often decide in favor of the latter kind of electrode.

2.1.4.1 Selection of Experimental Conditions The experimental conditions for either catalyst or substrate determination can be decided using the kinetic zone diagram.[47] This shows the occurrence of various kinetic regimes as a function of two dimensionless parameters that include both intrinsic (rate constants) and operational factors (the timescale and reactant concentrations). The simplest procedure for dealing with the kinetic data corresponds to limiting kinetic regimes and such conditions are also optimal for analytical determination. Figure 2 shows the kinetic zone diagram for the $E_rC'_{ir}$ mechanism under the conditions of LSV. The relevant parameters are $\gamma = c_A^0/c_P^0$ (the excess factor) and $\lambda_1 = (k_1 c_P^0/v)(RT/F)$. The arrows on the right-hand side of the figure represent the direction and the magnitude (in log units) of the shift produced by intrinsic (k_1) and operational (v, c_A^0, c_P^0) factors.

In the purely kinetic zone K, fast substrate consumption leads to a purely kinetic regime involving mutual compensation between the parallel chemical reaction and the diffusion process. A limiting case of this situation that corresponds to a very low λ_1/γ ratio is represented by

Figure 2 Kinetic zone diagram for the $E_rC'_{ir}$ mechanism in LSV. (Adapted from Savéant and Su.[47])

the KS zone. Here the substrate concentration is constant throughout the solution and the diffusion effect is negligible. Consequently, the voltammogram shows the characteristics of the steady state, that is, it is S-shaped, with the half-wave potential equal to $E^0_{P/Q}$ and the plateau current is in accord with Equation (17), i.e. directly proportional to c^0_P. Such conditions are suitable for catalyst determination with the sensitivity proportional to $(c^0_A)^{1/2}$.

In the opposite case of total catalysis (KT), the substrate consumption is so fast that the rate-determining step is the diffusion of the substrate. This makes this kinetic zone suitable for substrate determination. Under these conditions, the catalytic process produces a peak located well ahead of the standard potential of the P/Q couple.

The KD zone represents the transition from pure diffusion control (no catalysis) to pure kinetic control. In the KG and KG* zones, some complications arise from the tendency of the voltammogram to split into two waves, the potential separation and relative heights of which are functions of both λ_1 and γ.

As is usual in kinetic analysis, the signal is strongly dependent on the chemistry of the system. The mediator-binding ligands (activators) may strongly influence the rate of the regeneration reaction and its proper selection will improve the sensitivity dramatically. The pH is also an important factor, as it may influence various processes such as metal ion hydrolysis, complex formation and substrate protonation. The presence of radical scavengers, with negative effects on sensitivity, has to be avoided. Temperature should be carefully controlled in view of its strong effect on the catalytic current via the rate constant k_1. However, this could be an advantage as the sensitivity strongly increases with temperature.

It is also worth mentioning the potential applications of electrocatalysis in microheterogeneous fluids. Surfactant aggregates (micelles, microemulsion) can enhance the rate of the parallel reaction by bringing the reactants together in local higher concentrations. This results in enhanced sensitivity and makes nonpolar substances amenable to electroanalysis in an aqueous milieu.[48]

2.1.4.2 Catalyst Determination This is by far the most important analytical application of redox catalysis at bare electrodes, enabling an appreciable enhancement in sensitivity. Substrate selection is important for achieving convenient analytical figures of merit. First, the substrate must be selected taking into account its redox potential with respect to that of the mediator (section 2.1.1). Additionally, a high rate constant for the parallel reaction, as well as some affinity of the substrate towards the mediator, may improve the sensitivity.[45] Although dated, the survey by Mark and Rechnitz[49] of the redox reactions from the kinetic viewpoint provides a good theoretical starting point for rationalizing the analytical applications of redox catalytic electrode processes. More recent monographs afford a deeper insight of the molecular basis of redox reaction.[50]

Most of the early applications of redox catalysis at bare electrodes have been reviewed[44] and refer to industrial, geological and biological samples. The most impressive progress in this field results from the combination of ASV with redox catalytic processes. In ASV the preconcentration is made by the adsorption of the analyte (here, a metal ion in complex form) on the electrode surface at an appropriate potential. During the subsequent potential scan, the adsorbed species undergoes an electrode reaction that produces the analytical signal as a current peak.[51] This method is very convenient for the determination of most of the transition metals that cannot be concentrated as an amalgam in the mercury drop electrode. If the electrode reaction is accompanied by a redox reaction, which regenerates the initial form, the sensitivity is greatly enhanced. Also, the selectivity can be ameliorated in this way. The selection of the ligand is crucial – it must possess a high surface activity so as to enable the adsorptive preconcentration and it must not alter the redox properties of the analyte. It is particularly advantageous that the ligand (which is usually added in excess) also does act as a substrate. In this case, the parallel reaction involves two adsorbed partners and the reaction rate may increase accordingly.

Some selected examples of analytical applications of redox catalysis at bare electrodes are included in Table 1.

2.1.4.3 Substrate or Ligand Determination The catalytic determination of the substrate may be advantageous from several standpoints. First, it makes possible

Table 1 Selected examples of voltammetric methods of analysis using catalytic redox processes for signal enhacement

Analyte	Ligand (L)	Substrate	Supporting electrolyte	Method[a]	Detection limit (M)	Ref.
Co	Dimethylglyoxime (0.1 mM)	NO_2^- (0.5 M)	0.1 M Ammonia/ ammonium chloride buffer	LS–ACSV: $E_d = -0.5$ V (Ag|AgCl (3 M KCl))	1×10^{-10}	52
$Cr^{III} + Cr^{VI}$ (in natural water samples)	Diethylenetriamine-pentaacetic acid (DTPA) (0.01 M)	NO_3^- (0.5 M)	0.04 M CH_3COONa, pH 6.2	DP–ACSV: $E_d = -1.0$ V (Ag|AgCl (sat. KCl))	5×10^{-10}	53
Fe^{III} and Fe^{II} (in seawater)	1-Nitroso-2-naphtol (20 μM)	BrO_3^- (40 mM)	0.01 M HEPES buffer (pH 8)	LS–ACSV: $E_d = -0.05$ to -0.04 V (Ag|AgCl (3 M KCl))	8×10^{-11}	54
Ge (in soils and vegetables)	Catechol (1.5 mM)	BrO_3^- (0.1 M)	0.07 M Acetate buffer (pH 4.6)	DC polarography	10^{-9}	55
Mo and W (in seawater)	Benzilic acid (0.3 mM) + 2-methyl-8-quinolinol (0.2 mM)	ClO_3^- (0.5 M)	0.03 M H_2SO_4	DC polarography (after preconcentration on a resin column)	5×10^{-10} (Mo) 5×10^{-11} (W)	56
Ti (in seawater)	Mandelic acid (4 mM)	ClO_3^- (45 mM)	NH_4Cl, pH 3	DP–ACSV: $E_d = -0.1$ V (Ag|AgCl (3 M KCl))	10^{-12}	57
Ti (in pure Al)	Cupferron[b] (0.1 mM)	Cupferron	0.1 M HCl in 10% v/v ethanol	LS–ACSV: $E_d = -0.2$ V (SCE)	6×10^{-11}	58
Ti and Mo (in natural water)	Mandelic acid (4 mM)	ClO_3^- (45 mM)	NH_4Cl, pH 3	DP–ACSV: $E_d = -0.1$ V (Ag|AgCl (3 M KCl))	10^{-10} (Mo) 10^{-9} (Ti)	59
U (in ground and river water)	Cupferron[b] (0.005 mM)	Cupferron	Acetate buffer (0.1 M, pH 4.5)	DP–ACSV ($E_d = -0.2$ V) or on-line DP–ACSV flow analysis	4×10^{-10}	60
V	Cupferron (0.02 mM)	BrO_3^- (6 mM)	5 mM Acetate buffer (pH 4.8)	DP–ACSV, $E_d = +0.1$ V	5×10^{-12}	61

[b] The ligand also acts as a substrate/oxidant.

the determination of some compounds that show electrochemical properties not suitable for electroanalytical quantitation. Second, the electrochemical process proper involves the mediator and, by an appropriate mediator selection, the electrochemical response may be shifted beneficially along the potential axis. No special advantages from the standpoint of sensitivity can be expected under the conditions of the steady-state methods (namely DC polarography and RDE voltammetry) because the response cannot overcome the diffusion current of the substrate. However, the sensitivity and detection limit can be substantially improved when using nonsteady-state methods (e.g. DPP, SWV or AC polarography) provided that the mediator undergoes a reversible electrode reaction. This advantage results from the dependence of the response on the rate constant for the electrode reaction, k_s. An important detail related to the form of the calibration graph is the occurrence of a nonzero signal even in the absence of the analyte substrate. This is due to the simple electrode reaction of the mediator.

Although not so frequent as the applications for catalyst determination, the catalytic substrate determination may prove very useful as, for example, in the determination of trace nitrate (with U^{VI} as catalyst),[62] H_2O_2 (on a copper electrode, with anodically generated Cu^I as catalyst),[63] hydrazine,[46] or hydroxylamine[64]

(with 4-hydroxy-2,2,6,6-tetramethyl-piperidin-1-oxyl as catalyst).

Catalytic redox processes may also be used for the determination of a ligand, provided that the complex compound differs from the noncomplexed mediator in both the standard potential and catalytic activity. The distinct wave of the complex is amplified by an appropriate substrate in order to improve the sensitivity. In this respect, the determination of some hydroxyacids and polyphenols using either the $Ti^{IV}-ClO_3^-$ or $Mo^{VI}-ClO_3^-$ systems has been investigated.[45] Analogously, phosphate ion may be determined as molybdophosphoric acid in the presence of ClO_3^-.[65] Nitrite ion may be determined after disproportionation to nitrogen oxide which is thereafter included in the $[Fe(SCN)(NO)]^+$ complex. This gives a catalytic current in the presence of dissolved oxygen.[66]

2.2 Indirect Electrocatalytic Methods

This class of methods includes electrode processes with no electron transfer to or from the catalyst species. Interaction with the substrate occurs so as to decrease the activation energy of the electrode reaction and thus generates a new electrochemical signal with a distinct position on the potential axis.

2.2.1 Ligand-catalyzed Metal Ion Reduction

The catalytic reduction of some metal ions was first detected for Ni^{2+} or Co^{2+} by DC polarography in the presence of some aromatic diamines,[67] pyridine or its derivatives,[67,68] and aminothiols such as cysteine and its derivatives.[69–71]

The catalytic process induces a prewave whose half-wave potential may be hundreds of millivolts positive with respect to that of the main (irreversible) wave due to the hydrated metal ion, M^{n+} (Figure 3). It is obvious that a complex compound is reduced in the potential range of the prewave. The catalytic character of this process is demonstrated by the high i_k/i_d ratio, where i_k is the limiting current of the prewave and i_d denotes the expected diffusion current of the reducible complex compound. That is, the catalytic prewave occurs at a very low ligand/metal ratio, usually less than 0.1. The solution pH is an important parameter that decides the occurrence of the prewave via the formation of the reducible complex. Very often, the prewave is bell shaped (Figure 3).

An elementary description of the catalytic reduction of the metal ion is given by Equations (29) and (30) where L is the ligand catalyst (Scheme 2). The charges for L and the complex species are omitted for simplicity.

Provided that the metal ion is present in high excess and is not significantly depleted, the rate-determining

Figure 3 Catalytic nickel prewave (B) and catalytic hydrogen prewave (C) in the presence of cysteine. The background electrolyte is phosphate–acetate buffer, pH 6.5. Ni^{2+} concentration is 2×10^{-4} M (the nickel diffusion wave is indicated as (A)). Cysteine concentrations: (1) 0 M; (2) 6×10^{-5} M.

$$[ML] + ne^- \longrightarrow M(0) + L \quad (29)$$

$$L + M^{n+} \rightleftharpoons [ML] \quad (30)$$

Scheme 2

step is the regeneration of the reducible complex. This characteristic is demonstrated by the absence of any mass transfer effect on the prewave current. Experimentally, the absence of any effect of the mercury column pressure (in DC polarography[72]) or potential scan speed (in LSV on a stationary electrode[73,74]) is an indication of kinetic control by the chemical regeneration step.

This simple reaction scheme is often complicated by additional factors: ligand protonation; occurrence of a series of successive complexes; ligand adsorption (often under nonequilibrium conditions); the effect of electrode potential on the adsorption degree; and double-layer effects on the concentrations of charged reactants in the reaction layer. Attempts to set up a theoretical approach taking into account the above factors yielded only a partial description of the process.[67,68] However, a search for

systems showing simpler behavior enabled the catalytic current theory presented in section 2.1.2 to be used, by substituting [ML] for P, L for Q, and M^{n+} for A. This procedure is suitable in the absence of adsorption and if the formation of higher complexes is prevented. In this way, either DC polarography or LSV has been used for the determination of rate and equilibrium constants for the parallel, complex-forming reaction in the case of nickel reduction catalyzed by nicotinamide[72,73] or 6-mercaptopurine riboside.[74]

When the ligand adsorption has to be accounted for, two main problems arise. First, when using the dropping mercury electrode, the surface concentration is not accurately given by an adsorption isotherm because the equilibrium state cannot be achieved during the short lifetime of each drop. Conversely, if a hanging mercury electrode is used instead, the adsorption equilibrium could be attained by a prolonged contact with the solution at a given potential. However, during the potential scan, the equilibrium is disturbed by the shift in the value of the adsorption coefficient.[75] A favorable situation arises when the diffusion-controlled adsorption of the catalyst is the rate-determining step because, under such conditions, the kinetic equation relating the current to catalyst and reactant concentration can be derived.[71]

As far as the stoichiometry of the reducible complex is concerned, a direct correlation of the equilibrium data with the prewave current in the Ni^{2+}–penicillamine system demonstrated that the metal/ligand ratio is 1 : 1.[76] This value is similar to that determined in an indirect way for other ligands[71,72,74] and seems to be typical for the catalytic reduction of the metal ion.

The catalytic prewave of the metal ion enables sensitive determination of the ligand catalyst, which may be electrochemically inactive and not amenable to electrochemical determination by other methods. The sensitive determination of pyridine,[67] methionine,[77] or the alkaloid pilocarpine[78] in the presence of Ni^{2+} can be mentioned as examples. Noteworthy progress in this field has emerged by using catalytic reduction of the metal ion as a detection process in stripping voltammetry.[79–82] Detection limits down to 10^{-9} M can be achieved in this way for compounds showing catalytic properties in the reduction of Ni^{2+} or Co^{2+}.

Moreover, the dependence of catalytic activity on subtle features of the catalyst structure enables selective determination of the catalyst in the presence of related compounds. For example, *o*-phenylenediamine can thus be determined in the presence of its meta or para isomers by DC polarography.[67] Analogously, cysteinyl dipeptides have been determined in the presence of their constituent amino acids.[71] Cathodic stripping voltammetry allows the simultaneous determination of either cysteine or penicillamine (as a catalyst) and *N*-acetyl cysteine (a noncatalytic compound) in the presence of Ni^{2+}.[79,80]

Figure 4 Catalytic hydrogen evolution on the dropping mercury electrode produced by an organic base. Curve 1 – background electrolyte alone (0.05 M borax, pH 9.2). Curve 2 – as for 1, with 3×10^{-6} M quinine as catalyst.

2.2.2 *Hydrogen Evolution on Mercury Electrodes Catalyzed by Organic Bases*

Hydrogen evolution on the mercury electrode occurs with an extremely high overvoltage. Some organic compounds (proteins, various alkaloids, pyridines and their derivatives, other heterocyclic nitrogen compounds) may reduce the hydrogen overvoltage giving a typical polarographic wave (Figure 4). Its current is much higher than any expected diffusion current in the system. This wave was ascribed a catalytic character[83] and is sometimes called a presodium wave, in view of the experimental circumstances that led to its discovery. The organic catalyst must be able to bind a proton, which subsequently enters the electrode reaction. That is why the catalytic wave obviously occurs in buffer solutions at a pH close to the pK_a of the catalyst.

Several interpretations of the catalytic hydrogen evolution by organic nitrogen bases have been proposed.[83] The most elaborate[84] postulates that the electron uptake by the protonated catalyst (BH^+) produces a radical, BH•. Thereafter, the radical dimerizes leading to regeneration of the catalyst in the nonprotonated form ($2BH\bullet \longrightarrow 2B + H_2$). The B• form is subsequently protonated via reaction with the acid component of the buffer. The bell-shaped form of the catalytic wave was explained by two opposite effects of the potential shift towards more negative values – an increase in the rate constant for the electron transfer reaction (according to the Butler–Volmer equation), and a drop in the surface concentration of the catalyst.

This interpretation was recently criticized from two standpoints.[85,86] First, it is stressed that the catalyst is a reduction product of the nitrogen base present in the solution and not the base itself. Second, a key step in the mechanism, i.e. dihydrogen production by radical dimerization, has never been proved directly by the methods of organic chemistry.

Despite the uncertain mechanism, this electrode process has proved useful in the very sensitive determination of various compounds of pharmaceutical relevance.[87] Catalytic hydrogen evolution has been used as a detection process in ASV for the determination of either anticancer alkaloids,[88] or ammonia (after reacting it with formaldehyde to give methyleneimine).[89]

2.2.3 *Platinum Metals Catalysis of Hydrogen Evolution on Mercury Electrodes*

The wave recorded in acidic solutions containing platinum metal ions was ascribed to hydrogen evolution on metal microcrystals that form on the mercury electrode surface by metal ion reduction.[83] The wave height increases in the sequence $Ru^{III} > Rh^{III} > Ir^{IV} > Pt^{IV} > Pd^{IV}$ and enables extremely sensitive determinations (e.g. $5-10^{-10}$ M ruthenium).

More recently it has been shown that some platinum complexes with organic ligands (such as ethylenediamine[90,91] or formazone[92,93]) behave analogously. Moreover, the organic ligand enables adsorptive accumulation of the metal ion in view of the stripping voltammetric determination with detection by means of the catalytic hydrogen current.[88,93] It is thus possible to detect Pt at the ultratrace level in biological, environmental and geological samples. The ligand itself, or a compound that generates the ligand by an appropriate chemical reaction, can also be determined in this way.[94] Analogous applications for other platinum group metals have been reported.

2.2.4 *Hydrogen Evolution on Mercury Electrodes Catalyzed by Transition Metal Complexes*

The most typical behavior of this feature is shown by sulfur-containing amino acids or proteins in the presence of cobalt ions in the ammonia buffer at pH about 9.5. The catalytic wave occurs in the potential range of the diffusion current for Co^{2+} reduction and has the shape of a round maximum in the case of the small molecular mass compounds (Figure 5). Under the same conditions, proteins give a particular double wave (Figure 6).[83,95–98] This kind of polarographic wave is often termed a Brdička wave after the name of the discoverer. Under the same conditions, Ni^{2+} gives lower catalytic currents. Analogous electrode processes may occur in the presence of other ligands containing sulfur, selenium, nitrogen or phosphorus.[97]

Figure 5 Catalytic hydrogen evolution on the dropping mercury electrode produced by Co^{2+} (5×10^{-4} M) and cysteine. Background electrolyte was NH_3, NH_4Cl (0.1 M each) +0.005% gelatine. Cysteine concentrations: (1) 0 μM; (2) 1 μM; (3) 2 μM.

Figure 6 Brdička double wave of protein. (Curve 1) NH_3, NH_4Cl (0.1 M each) and $Co(NH_3)_6Cl_3$, 0.001 M. (Curve 2) 400 times diluted blood serum added. Electrochemical reactions are (A) $Co^{3+} \longrightarrow Co^{2+}$, (B) $Co^{2+} \longrightarrow Co$, and (C) catalytic double wave. Wave B on curve 1 shows a first-order polarographic maximum that is removed by protein adsorption in the case of curve 2. (Adapted from Heyrovský and Kůta.[83])

It is clear that the catalytic wave is due to a metal complex, which must be present at the electrode surface. A common feature is that the ligand is strongly polarizable and may accept electron pairs from the metal ion in an empty π or d orbital. In this way, unusual low-valence states of the metal ion (+1 or 0) may be stabilized. The catalytic complex is usually a chelate species, although this is not a general rule.

Two different assumptions have been made about the nature of the catalytic complex. The first assumes that this complex contains the metal ion in the normal oxidation state (2+), but its reduction potential is shifted to more negative values as an effect of complexation.[97] This complex is reduced in the potential range of the catalytic wave, simultaneously with catalytic hydrogen evolution. Consequently, the gradual decrease in the interface concentration of the catalytic complex produces a drop in the wave current after reaching a maximum (Figure 5).

The alternative interpretation assumes the catalyst to be a zero-charged metal complex, which results from the electroreduction of the normal complex present in the solution.[98] In this instance, the round shape of the catalytic hydrogen wave may be ascribed to the effect of the electrode potential on the surface concentration of the adsorbed organic ligand.[84] It is possible that either of the above mechanisms may be operative, depending on the properties of the ligand. As a common detail, both interpretations point out that the maximum current is not a true limiting current.

The occurrence of a double wave in the case of the proteins may be due to either the occurrence of two catalytic complexes with different properties[97] or to some changes in the adsorption layer due to the shift in the potential value.[84] Despite the complexity of the reaction mechanism, the effect of some experimental parameters on the protein double wave is fairly accounted for by the equations derived under the assumption of the diffusion-controlled catalyst adsorption.[99]

A more advanced decrease in hydrogen overvoltage on the mercury electrode occurs in the presence of Ni^{2+} and cysteine or related compounds, at pH 6–7.[100,101] The catalytic hydrogen prewave thus produced ($E_{1/2}$ about -1.2 V versus SCE; Figure 3) shows many distinct characteristics when compared with the Brdička wave and is much more sensitive to small changes in ligand structure. In this instance, the occurrence of hydride ion as an intermediate that coordinates the metal center is highly probable, in accord with recent representations of hydrogen evolution catalyzed by metal complexes.[102] The relevant electrode process was suggested as a model for hydrogenase-catalyzed hydrogen bioproduction.[101,103]

Catalytic hydrogen evolution enables very sensitive determination of the organic ligand, and various applications in biochemistry and medicine have been reported.[96] Much effort has been devoted to establishing a cancer test based on the Brdička wave.[95,96] Although such a method appears now to be of purely historic interest, the Brdička reaction still proves useful in some applications.[104–106] After being optimized for DPP, it now enables the determination of minute amounts of proteins (0.1–1 mg L^{-1}).[107] In this version, it is one of the standard methods for the determination of metallothionein.[108,109] The Brdička wave also enables the simultaneous determination of hemoglobin and cysteine.[110] Other sulfur-containing organic compounds may be similarly determined.[111,112]

The catalytic hydrogen evolution in the Co^{2+}–SH^{-} system has been employed as a detection process in cathodic stripping voltammetry of sulfide ion on the mercury electrode.[113] Some organic sulfur-containing compounds can be determined in the same way after the carbon–sulfur bond splits during the deposition step at a sufficiently positive potential.[114]

The catalytic wave is also useful for the determination of the metal ion itself, as a component of the catalytic complex. This method brings about a spectacular enhancement in sensitivity. Accordingly, the most important electroanalytical methods for nickel and cobalt determination are based on the catalytic hydrogen evolution in the presence of dimethylglyoxime.[115] The catalytic ligand may also enable adsorptive preconcentration of the metal ion on the hanging mercury drop electrode, in view of the stripping voltammetric determination, with detection by the catalytic evolution of hydrogen.[115,116]

Some metal complexes of practical importance (e.g. fungicides) can be determined by the catalytic wave induced by the constituent sulfur-containing ligand.[117] Some metal ions can also be determined indirectly, after performing the extraction as a chelate with a ligand that is able to produce the catalytic hydrogen wave (dithiocarbamates, xantogenates, 8-mercaptoquinoline).[117]

3 ELECTROCATALYSIS AT CHEMICALLY MODIFIED ELECTRODES

3.1 General Aspects

The properties of the electrode can be deliberately modified by immobilizing a reagent on its surface so that the modified electrode displays the properties of the immobilized compound. Reagent immobilization can be done by chemical (irreversible) adsorption, covalent bonding, or film deposition.[118,119] The composite electrodes, consisting of a mixture of conducting powder (e.g. carbon), a modifier and a hydrophobic binder, may also be included in this class. Depending on the modifier properties, the electrode may achieve various functions, such as preconcentration of the analyte, permselectivity, detection of some electroinactive species, or electrocatalysis.

As a research field, electrocatalysis at a CME is mostly directed towards mediated electron transfer via an immobilized redox couple. An immobilized redox couple may act as a shuttle for electron transfer between

Figure 7 Diagram of mediated electron transfer at a CME for an oxidation process.

the electrode and some substrate, which would otherwise undergo a slow electrochemical reaction. This process is fairly described by Equations (5–7) with the important difference that the mediator is bound to the electrode surface and only the substrate and the products take part in mass transfer processes in the bulk of the solution (Figure 7). The catalyzed reaction often involves the transfer of several electrons, the breaking of some chemical bonds and the formation of new ones. In order to increase the reaction rate for such a complicated process, some intermediate must be stabilized by interaction with the modifier.

The thermodynamic requirement for electrocatalysis to occur is the same as for the homogeneous system (section 2.1.1). The catalyzed reaction proceeds at the formal potential of the mediator couple, provided that no catalyst–substrate adduct forms (Figure 8). The mediator must be able to undergo a very fast electron transfer

Figure 8 CV data demonstrating the electrocatalysis of hydroxylamine oxidation at a CME (glassy carbon electrode modified with a cobalt(II) hexacyanoferrate film). Background electrolyte, acetate buffer (pH 4.5), 0.1 M $NaNO_3$; scan rate, $0.1\,V\,s^{-1}$. (a) Bare carbon electrode, 9 mM NH_2OH. (b) Modified electrode, no NH_2OH (the CV peaks are due to the electrochemical processes involving the immobilized modifier). (c, d) As (b) with 6 and 9 mM NH_2OH, respectively. (Adapted from Chen.[133])

reaction, i.e. the reorganization of the coordination sphere should involve a small Gibbs energy change. This condition is fulfilled by complexes of transition metals (e.g. ferrocene and cyano complexes of iron and ruthenium) and organic molecules with a large π-bond system (e.g. phenoxazine, tetrathiafulvalinium tetracyanoquinodimethane (TCNQ)). A comprehensive description of various mediators with modified carbon electrodes is available.[120]

Metal powders dispersed in a conductive matrix are efficient catalysts for the electrooxidation of various organic compounds. Specific interaction with the substrate rather than mediated electron transfer may be the source of the catalytic activity in this instance.

3.2 The Modifier as a Thin Layer

Submonolayer or monolayer coverage is achieved by irreversible adsorption from solution or by placing a small, accurately measured volume of the modifier solution on the electrode surface and letting the solvent evaporate. This straightforward method suffers from a poor reproducibility, and leaching of the modifier slowly damages the resulting layer. It is still useful for a preliminary investigation of some modifiers.[118,119]

3.3 Electrocatalysis at Redox Polymer Modified Electrodes

3.3.1 Homogeneous Polymer Films

A redox polymer contains spatially localized redox sites. They can be bound covalently by being built into the chain or as a pendant group, such as osmium and ruthenium poly(pyridyl) polymers.[121] An alternative is electrostatic binding to an ion-exchange polymeric system, such as $Ru(bpy)_3^{3+/2+}$ included in a Nafion™ layer. In contrast to the monolayer, the polymer film forms a tridimensional structure containing up to $5 \times 10^{-6}\,mol\,cm^{-2}$ redox groups, providing a far greater number of reactive sites.

Most polymer modification procedures can be classified as either deposition of preformed polymers or electrochemical polymerization. Charge transport inside the polymer layer occurs by an electron exchange process between neighboring sites (self-exchange reactions, electron hopping, and redox conduction are alternative terms for this process). Simultaneously, transport of the co-ion in the opposite direction occurs to preserve electroneutrality, which is why the nature and the concentration of the background electrolyte may play a very important role in the charge transport process.

Redox catalysis at a CME occurs via a substrate–mediator electron-transfer reaction that may proceed either at the outer surface of the polymer film (surface reaction), or inside the coating with the substrate undergoing diffusion within the modifier layer.[122–124]

Two different theoretical models, leading to similar results, are commonly quoted. In the model of Albery and Hillman[125] two reaction layers are assumed. The first, located close to the film/electrolyte interface, is the zone where the substrate reaction with the mediator occurs. The other (near the electrode/film interface) corresponds to the electron transfer to (or from) the mediator. In the approach of Savéant et al.[126,127] no reaction layers are identified but the process is described in terms of four characteristic currents: substrate diffusion in the solution; substrate diffusion across the film; diffusion-like electron transfer across the film; cross-exchange between the redox center and substrate in the film. Steady-state methods (e.g. RDE[126] or UME[128,129]) provide the best conditions for the kinetic analysis of the catalyzed reactions at CMEs.

3.3.2 Microheterogeneous Polymer Layers

As previously discussed, the modifier film performs two parallel functions simultaneously, namely charge transport to the catalytic site and the catalytic activity. Conversely, a distinct component fulfills each function in the case of a microheterogeneous polymer. This provides more flexibility when designing a CME for a selected purpose. The coating may contain metal or metal oxide microparticles dispersed inside an electronically conducting polymer (polypyrrole, polyaniline), an ionically conducting polymer (Nafion™), or a redox polymer. The kinetic analysis of such a system must take into account two additional factors: substrate diffusion towards the catalyst particle within the matrix, and the charge transfer reaction at the particle surface.[122–124]

3.4 Electrodes Modified by Inorganic Films

Electrodes modified with sparingly soluble inorganic films promise better stability than polymer film CMEs.[130] For example, metallophthalocyanines and porphirines, as components of composite modified electrodes, are efficient catalysts for the oxidation of hydrazine, hydroxylamine, sulfhydryl compounds, α-keto acids and ascorbic acid[130,131] or for the reduction of oxygen, nitrate ion, and nitrogen oxide.[130]

Zeolites and clays show the particular advantage of performing size and shape discrimination. Although electrochemistry at zeolite and clay CMEs is a very dynamic field,[132] the analytical applications of electrocatalysis in such systems are still rather scarce.

Films of Prussian blue or its analogs ($KMe^{II}Fe^{III}(CN)_6$; Me = Fe, Co or Ni) can be formed on the electrode surface by electrolysis in a solution containing $Fe(CN)_6^{3-}$ and Me^{2+} ions. Such films display both intrinsic redox properties and also some size/shape exclusion characteristics. The oxidation of hydrazine, hydroxylamine, nitrite[133] and As^{III},[130] as well as reduction of O_2, H_2O_2 and Fe^{III},[130] are examples of electrochemical reactions catalyzed by such CMEs.

Other inorganic films with promising properties have been reviewed.[130] Lower metal oxides (PtOH, AuOH), nonstoichiometric, mixed-valence metal oxides (tungsten and molybdenum bronzes), and doped metal oxides show catalytic properties towards the oxidation of various organic compounds.

3.5 Carbon Paste Electrodes and Other Composite Electrodes

Graphite powder (5–20 μm particles) is mixed with an inert binder, such as paraffin or mineral oil, to form a paste that is typically 70% carbon by weight. The paste is packed into a shallow well in an inert holder with electrical contact at the back. A solid composite electrode may be prepared by using a filler like Kel-F™, Teflon®, epoxy resin or polyethylene.[134] To prepare a CME, a modifier reagent is either dissolved in the binder or physically mixed with the paste.[134,135] This is one of the most straightforward ways to prepare CMEs with highly reproducible properties.[134,136] Screen-printed electrodes, prepared by adding the catalyst to carbon ink,[137] can be also included in this class. A large diversity of inorganic (metal phthalocyanines, metalloporphyrins, hexacyanoferrates(III), metal powders, metal oxides and various complexes) or organic (phenoxazines, phenothiazines, quinone/hydroquinone) redox mediators are effective modifiers for carbon paste electrodes.

3.6 Electrocatalysis at Electronically Conducting Polymer Electrodes

In contrast to a redox polymer that contains distinct redox sites separated by nonconducting molecular fragments, an electronically conducting polymer (such as polypyrrole, polythiophene and their analogs) possesses extended π orbitals that facilitate continuous electron flow along the macromolecule. In some cases electrocatalytic activity is ascribed to the polymer itself, with no additional components. Thus the electrocatalytic mechanism may not be redox-mediated electron transfer, but the result of some favorable interaction between the substrate or some intermediates and the organic electrode surface. Some promising applications (for the detection of neurotransmitters, ascorbic acid, and other compounds of biological relevance) have been reviewed.[138]

3.7 Guidelines for Analytical Applications of Electrocatalysis at Chemically Modified Electrodes

From the analytical standpoint, electrocatalysis at CMEs can be used in two ways: the determination of the substrate by means of the catalyst-modified electrode; and for the determination of the catalyst by an electrochemical stripping method, after its accumulation on a properly designed CME.[139]

Substrate determination represents by far the most frequent application of CMEs for the analysis of various samples of environmental, biomedical and biotechnological relevance.[120,130,132,134,136–138,140–142]

Optimum conditions for electrocatalytic determination of the substrate at a CME are met when the rate-determining step is the mass transfer of the analyte in solution while charge propagation within the film is very fast.[142] A linear calibration graph results under such conditions and the kinetic complications are absent. Inorganic species appropriate for quantitation by such a method include oxygen, hydrogen peroxide, hydrazine, hydroxylamine, nitrogen and sulfur anions. Many more applications have been reported for organic and biochemical analyses (cysteine and derivatives, thiourea and derivatives, carbohydrates, polyalcohols, α-ketoacids).

Although CMEs have important advantages as sensors for batch analysis, the most promising applications are chemical sensors for field analysis, single-use sensors, and detectors for the analysis in flowing systems (flow injection analysis, liquid chromatography).[143] For detection in liquid chromatography, the problem of selectivity is not critical. Conversely, a low selectivity may be an advantage as it allows the detection of different compounds after performing the chromatographic separation. A serious problem with such detectors is the mechanical abrasion, but a permeable protecting coating over the catalytic layer can prevent this inconvenience.

As a result of their small size, modified UMEs have special advantages for microchemical-scale analysis, in vivo analysis,[144] or as detectors in capillary electrophoresis.[145]

4 AMPEROMETRIC ENZYMATIC DETERMINATIONS

4.1 Background

The outstanding specificity of enzymes as catalysts makes them very attractive for analytical purposes. Hence, enzymatic analysis is a well-established branch of analytical chemistry. Electrochemical methods can be used to monitor the enzymatic reaction occurring in the solution phase, but such a procedure is obviously not convenient owing to the consumption of the enzyme and other expensive reagents. The main interest in this field is therefore directed towards the development of electrochemical enzymatic sensors. The sensor consists of a reagent layer (including the enzyme) in close contact with a transducer that generates the measurable signal. The reagent layer performs the sensing (recognition) function by enzyme-catalyzed conversion of the substrate. Either potentiometric or amperometric transduction methods have been proposed, both showing some particular advantages. Whereas potentiometric transduction involves passive electrochemical devices, the amperometric version frequently relies on the integration of the electrochemical transducer in the electron transfer chain with the substrate at one end and the electrode at the other. At least one step in this dynamic process is an enzyme-catalyzed reaction, which justifies the classification of such procedures as electrocatalysis-based methods. Owing to the electrochemical nature of the transduction process, the most suitable enzymes belong to the oxido-reductase class, with glucose oxidase (GOD; EC 1.1.3.4) being a characteristic example.[146]

A simplified view of the function of an amperometric enzymatic sensor is described by Figure 9, for the particular case of substrate oxidation. Accordingly, the electron is transferred from the substrate S, to the cofactor $(CF)_{Ox}$, which is permanently or temporarily bound to the enzyme backbone. The reduced cofactor is thereafter reoxidized by a suitable electron acceptor, A_1.

Several transduction procedures have been proposed. The first involves the electrode reaction of the natural electron acceptor, A_1, or its product, A_2. Alternatively, an artificial mediator that shuttles the electrons from the prosthetic group of the enzyme to the electrode, through a regenerative process, may substitute the natural electron acceptor. Finally, it was attempted to perform the direct (nonmediated) electron transfer from the prosthetic group of the enzyme to the electrode. In this way, the electrode assumes the role of the cosubstrate A_1. It is sometimes claimed that only this latter case truly belongs to bioelectrocatalysis,[147,148] although such a sharp distinction in terminology overshadows some of

Figure 9 Simplified scheme of an enzymatic amperometric sensor.

the practical advantages. Any of the above three methods can be the basis for the transduction process.

4.2 Main Classes of Enzymes Used for Amperometric Sensors

Oxidases contain a redox cofactor that accepts electrons from the substrate and makes use of molecular oxygen as a reoxidation agent (electron and hydrogen ion acceptor, A_1 in the catalytic cycle). A typical example is the glucose sensor,[149] which is based on glucose oxidation by molecular oxygen catalyzed by GOD (Scheme 3). Here FAD (flavin adenine dinucleotide) represents the prosthetic group of GOD, formally acting as a cofactor.

Scheme 3

The transduction may be performed by monitoring either the concentration of O_2 (cathodic reaction) or that of H_2O_2 (anodic reaction).[150] Very often, this kind of sensor is said to be unmediated, because no artificial mediator is involved. However, from a mechanistic standpoint, the term ''unmediated sensor'' is more appropriate for that involving direct electron transfer between enzyme and electrode. The detection of either O_2 or H_2O_2 enjoys outstanding practical applications, but suffers some drawbacks that arise from interference by the electroactive compounds that are usually present in biological samples (ascorbic acid, glutathione, uric acid). In addition, these procedures are dependent on the pH and the oxygen content in the sample, and require additional manipulations (such as sample dilution with an oxygen-saturated buffer). Hence, artificial mediators are alternatively used to shuttle the electrons from the enzyme to an electrode. A typical example is represented by ferrocene (bis(η^5-cyclopentadienyl) iron) or its derivatives, which can be localized on a graphite foil in order to shuttle electrons from GOD to the electrode (Figure 10).[151–153] Ferrocene electrochemical oxidation is a reversible process that occurs at a low electrode potential, thus preventing the disturbing electrode reaction.

Dehydrogenases are enzymes that carry out their catalytic function with the help of an electron acceptor other than O_2. Nicotinamide adenine dinucleotide, (NAD^+/NADH) or nicotinamide adenine dinucleotide phosphate ($NADP^+$/NADPH) are low molecular redox cofactors that can accept (or donate, respectively) two electrons and a proton. A distinct class includes dehydrogenases acting on −CHOH groups (such as lactate dehydrogenase or glucose-6-phosphate dehydrogenase), according to Equation (31):

Figure 10 Electrocatalysis of glucose oxidation demonstrated by LSV at a graphite electrode in phosphate buffer (0.1 M, pH 7). (a) D-Glucose, 50 mM; ferrocenemonocarboxylic acid, 0.5 mM. (b) As for (a), but with the addition of 10.9 μM GOD.[151] The shape of the CV curve b is typical for a process with mediator regeneration as the rate-determining step and no substrate depletion (section 2.1.2.2).

$$NAD^+ + RR'CH{-}OH \longrightarrow NADH + RR'C{=}O + H^+ \quad (31)$$

Here, NAD(P) acts as a cosubstrate, i.e. it is temporarily bound to the enzyme molecule jointly with the substrate in order to perform the chemical conversion of the latter, whereas the redox regeneration of the factor occurs in the solution phase, after leaving the enzyme molecule. This characteristic represents a major advantage from the standpoint of coupling the enzymatic reaction with the electrochemical transduction process.

When using such enzymes, the transduction can be performed by the electrochemical oxidation of NAD^+, either by mediated electron transfer[152] or directly on organic salt electrodes.[152,154] Direct oxidation of NAD^+ on metal or carbon electrodes requires a high overvoltage and is disturbed by interference and secondary processes.

Over 250 enzymes belongs to this class, thus offering a wide range of analytical applications based on NAD(P) electrochemistry. The retention of the cofactor in the reaction layer, either by chemical immobilization or by an exclusion principle, is essential because of its solubility in water.

Table 2 Several versions of mono- and bienzyme sensors

Mechanism and designation	Analyte	Sensing process (enzyme reactions)	Transduction process	Response
Monoenzyme (sensor)	S	$S + A_1 \longrightarrow Pr + A_2$	$A_2 \pm ne \longrightarrow A_3$	Current increases with S concentration
			$A_1 \pm ne \longrightarrow A_3$	Current decreases with S concentration
Bienzyme (sequence sensor)	S	$S + A_1 \longrightarrow Z + A_2$ (enzyme 1) $Z + A_3 \longrightarrow Pr + A_4$ (enzyme 2)	$A_4 \pm ne \longrightarrow A_5$	Current increases with S concentration
Bienzyme (competition sensor)	Y	$S + A_1 \longrightarrow Pr + A_2$ (enzyme 1) $S + Y \longrightarrow A_3 + A_4$ (enzyme 2)	$A_2 \pm ne \longrightarrow A_5$	Current decreases with Y concentration
Bienzyme (substrate-recycling sensor)	S	$S + A_1 \longrightarrow Pr + A_2$ (enzyme 1) $Pr + A_3 \longrightarrow S + A_4$ (enzyme 2)	$A_2 \pm ne \longrightarrow A_5$	Current amplification due to substrate regeneration

Peroxidases are redox enzymes that can shuttle electrons to hydrogen peroxide (or small organic peroxides) from electron donors. The most common is horseradish peroxidase (HRP), which can accept electrons from virtually any reducing agent, such as ferrocyanide, phenol, *ortho*- and *para*-phenilenediamines, ascorbate, iodide, or ferrocene. The use of peroxidases in conjunction with hydrogen peroxide-producing oxidases is well established in analytical chemistry, including the field of amperometric biosensors.[141]

4.3 Configuration of the Enzymatic Amperometric Sensor

An enzyme amperometric sensor includes most of the features of a CME (section 3). The main problems when designing an enzyme sensor are concerned with the selection of the enzyme itself, the electrode material, additional reagents such as the mediator, and the procedures for the immobilization of enzyme and reagents. These problems are interrelated and must be dealt with in an integrative way, taking into account the expected figures of merit: sensitivity, the shape of the response function, the extent of the dynamic range, response time, and robustness.

Carbon is often the preferred electrode material, either in the form of carbon paste[155] or as a screen-printed electrode.[120,141,156] It is sometimes convenient to use a CME as a transducer instead of a plain electrode. For example, phthalocyanine-modified carbon electrodes are very convenient for the electrocatalytic detection of hydrogen peroxide produced in oxidase-catalyzed processes (e.g. glucose or uric acid sensors). Conducting organic salts, sometimes dubbed ''organic metals'', are the materials of choice for performing direct electron transfer to or from some biogenic compounds. Their use brings about a substantial simplification in sensor configuration.[154] Conducting organic salts are made by the combination of an electron donor with an acceptor. Such compounds are planar molecules with delocalized π-electron density, both above and below the molecular plane, and show a nonisotropic electrical conductance. A typical example in this class is the donor tetrathiafulvalene (TTF) combined with the acceptor TCNQ.

In addition to the obvious case of the monoenzyme sensor, inclusion of several enzymes is sometimes advantageous for interference removal (using an interferent-specific enzyme), mediated transduction using two mediators coupled with appropriate enzymes, indirect determination by competing enzyme reaction, or signal amplification by substrate recycling (Table 2).[157]

4.4 Immobilization Methods

Immobilization is a crucial step in preparing an enzymatic sensor. The purpose of this step is to produce an enzyme layer that is as thin as possible and to preserve the highest possible specific activity of the enzyme.

Any method of enzyme immobilization may be used to build up the sensing layer of an enzymatic sensor: immobilization behind a permselective membrane, covalent attachment to a membrane, entrapment in polymer gels, covalent cross-linking with bi- or multifunctional reagents, covalent coupling to a polymeric support or directly to the functionalized electrode surface.[158–160] The use of carbon as an electrode material has promoted immobilization into organic phase composite structures (carbon paste, carbon cement, carbon epoxy resins,[134,137,141,155] or screen-printed layers[141]). Either mono- or multilayers can be prepared by enzyme binding to the self-assembled monolayer of a functionalized thiol.[161,162]

Electropolymerized films[163–166] represent a very attractive way of preparing the enzyme layer as the polymers provide a favorable microenvironment for the enzyme. The preparation procedure is straightforward and easily monitored by the electrochemical parameters (sections 3.3 and 3.6). In addition, an electronically conducting polymer also can perform coupling of the electron transfer between the molecular species and the electrode.

Either entrapment of the enzyme during the electrochemical preparation of the polymer film or covalent binding to a functionalized polymer layer may be employed as the immobilization procedure. The second, multistep method is more flexible and offers more possibilities for securing the expected properties to the enzyme-containing modifier film. Alternatively, it is possible to perform electrochemical copolymerization of the plain monomer (e.g. pyrrole) and the enzyme-bound monomer.

Some changes in enzyme properties due to immobilization may occur. Hence, the evaluation of some parameters (such as recovery of enzyme activity, effectiveness factor, enzyme loading, sensor response and extension of the linear range, pH and temperature effects) enables the effectiveness of the immobilization method to be assessed.[160]

4.5 Redox Mediators for Amperometric Enzymatic Sensors

The use of a mediator makes the transduction process virtually independent of the ambient conditions and, simultaneously, shifts the working electrode potential to a convenient range, where the occurrence of a disturbing electrode reaction is less probable. An effective mediator is stable in both the oxidized and reduced forms; it should react rapidly with the enzyme and it should also exhibit a fast and reversible electrode reaction, with a low and pH-independent overpotential. The most frequently used artificial mediators include ferrocenes, hexacyanoferrate, phenoxazines, phenothiazines and phenazines, quinone/hydroquinone, TTF, and TCNQ.[120,146,152,155]

Electropolymerized films offer a very convenient alternative for the integration of redox mediators in the modifier layer. Negatively charged modifiers (ferro/ferricyanide, ferrocene carboxylate, and hydroquinonesulphonate) may be entrapped as counterions in electronically conducting polymers. The poor long-term stability of such systems, due to mediator leakage, has prompted the use of redox polymers (section 3.3) as the immobilization environment for the enzyme.[164,165] In this case, the polymer chain has to exhibit some flexibility so as to allow redox groups to reach an enzyme site.

4.6 Sensor Response: Modeling Enzyme Electrode Processes

A linear response over a broad concentration range is the ideal for any kind of sensor. Nevertheless, at least one step in the reaction sequence, namely the enzyme-catalyzed reaction, obeys a nonlinear kinetic equation and the situation is even more complicated in the case of the mediated electron transfer and multienzyme sensors. Consequently, careful optimization of sensor configuration, using both empirical and theoretical approaches, is essential for good performance. Generally, the electrode reaction, which represents the transduction process, is carried out with a sufficiently high overvoltage to make it very fast and kinetically irrelevant. The linear response occurs as a result of the mass transfer control of the overall reaction kinetics. Diffusion of the substrate or intermediate products through permselective membranes, or within the enzyme layer, could grant the appropriate mass transfer limitation.

The modeling of bioelectrocatalytic sensors is closely connected to the more general problem of mass transfer processes accompanied by reactions catalyzed by immobilized enzymes, a topic belonging to bioengineering.[167] Owing to the variety of sensor configurations, a general theoretical treatment is not possible. However, some general strategies have been outlined.[168–171]

In common with electrochemical kinetics, either mathematical analysis (using some numerical procedures) or digital simulation can be used to model the sensor process (see section 2.1.1). The most simple case is homogeneous mediation, which shows the characteristics of the EC′ mechanism (section 2.1) for the limiting case of very fast enzyme–substrate kinetics. This may be useful in preliminary investigations, but the actual sensor needs enzyme immobilization, and a series of additional factors must be considered: the number of enzyme reactions (Table 2); the number of layers (either reactive or protective); the kinetics of the enzyme reaction; the occurrence of either the steady state or transient behavior; the nature of the electroactive compound involved in the transduction process; and the required overvoltage. It is usually assumed that the diffusion proceeds along a single axis (planar diffusion) and obeys Fick's laws. It is clear that modeling the processes occurring in enzyme electrodes is not an easy task, but it provides substantial rewards – a better understanding of the mechanism and kinetics operating in the system, and a logical basis for the design and optimization of the sensor.

4.7 Examples of Applications

Amperometric enzymatic sensors represent the most successful class of biospecific sensors,[120,137,141,155,172,173] due mostly to the direct coupling of the recognition and transduction processes. They encompass the benefits of the dynamic electrode processes, such as linear response over a wide concentration range and the possibility of tuning the selectivity by the electrode potential.

The technological aspects of sensor production are an important area of research. It must be pointed out that an amperometric sensor is actually an electrochemical cell that needs, in addition to the sensing device, a reference electrode and, sometimes, an auxiliary electrode for operation in a three-electrode configuration. Modern

Table 3 Application of some commercial oxidase-based amperometric sensors using O_2 as the electron acceptor. (Adapted from J.R. Woodward, R.B. Spokane[177])

Analyte	Enzyme	Sample
Glucose	GOD	Blood, serum, plasma, dextrose in vegetables, ice cream, cereals, peanut butter
Sucrose	GOD/mutarotase/ invertase	Vegetables, ice cream, peanut butter, baked goods, cereal, effluent monitoring
Lactate		Blood, serum, plasma, spinal fluid; lunch meats, cooked foods
Lactose	Galactose oxidase	Cheese, whey
Ethanol, methanol	Alcohol oxidase	Alcohol in beers and wine; aspartame (after pretreatment with chymotrypsin)
Glutamate	Glutamate oxidase/ glutaminase	Glutamine in cell cultures
Choline	Choline oxidase	Infant formula, pet foods

microelectronics enables facile fabrication of the sensor, even for single-use application or at the micro scale, for in vivo measurements.[174,175] The use of microorganisms or tissue instead of isolated enzymes may achieve both operational and practical advantages.[155]

The applications of amperometric enzyme sensors encompass health care, the food and fermentation industries, defense, and environmental monitoring.[176] Glucose monitoring in blood is the first and still most widely used application, but other low-molecular-weight substances are currently determined by commercially available enzymatic sensors (Table 3).

5 CONCLUSIONS

Catalytic electrochemical processes may be used for analytical purposes either by adding the appropriate reagents to the sample solution or by including them in the structure of a CME. In the first case, the advantages of electrocatalysis are conveniently exploited using general-purpose devices such as the many versions of mercury electrodes. In the second case, it is possible to develop a specialized chemical sensor for field applications, single-use sensors, or detectors for the analysis in flowing fluids (flow injection analysis, liquid chromatography). Microdevices (UMEs, microchips) enable electrocatalysis-based sensors to perform analyses on very small sample volumes, in vivo analysis, or for detection in capillary electrophoresis. Analytical applications encompass a large variety of substances – from metal ions and simple inorganic species to various organic species, and many essential biological compounds.

LIST OF SYMBOLS

A	electrode area
$a = nFv/RT$	dimensionless sweep rate in LSV for a reversible electrode reaction
$b = \alpha nFv/RT$	dimensionless sweep rate in LSV for an irreversible electrode reaction
c	concentration of the species indicated by the subscript. The superscript "0" refers to bulk (equilibrium) concentration
D	diffusion coefficient
E	electrode potential (on the standard hydrogen electrode scale)
E^0	standard redox potential for the redox couple shown by the subscript
$E_{1/2}$	half-wave potential
E_e	equilibrium electrode potential
E_i	initial potential in LSV
F	Faraday constant
h	the height of the mercury level above the lower end of the mercury capillary electrode
i	electrolytic current
i_c	catalytic current
i_d	diffusion current
i_0	exchange current
i_k	limiting current of the metal ion catalytic prewave
k	rate constant for Equation (7)
k_1, k_2	homogeneous forward and backward rate constants, respectively, for the regeneration step
k_3	rate constant for the intramolecular electron transfer inside the catalyst–substrate adduct
K_a	acid ionization constant
K_{QA}	equilibrium constant for the formation of the catalyst–substrate adduct
k_s	conditional rate constant for the electrode reaction
n	stoichiometric coefficient of the electron in the electrode reaction
p	square-wave period in SWV
q	dimensionless potential sweep rate for LSV at a UME

R	gas constant
r_d	disc UME radius
r_s	spherical UME radius
T	absolute temperature
t	time variable
t_1	drop-time for the dropping mercury electrode
v	potential scan rate
α	transfer coefficient
δ	the thickness of the convection-free solution layer at electrode surface (diffusion layer)
χ_1	dimensionless kinetic parameter in DC polarography
Γ	surface coverage
η	overvoltage
Λ_s	dimensionless kinetic parameter for the case of the heterogeneous regeneration reaction with no substrate–catalyst adduct formation
Λ_m	dimensionless kinetic parameter for redox catalysis at a UME
ν	cinematic viscosity
Θ	dimensionless kinetic parameter for the case of the heterogeneous regeneration reaction with substrate–catalyst formation
τ	pulse duration in DPP; more generally, characteristic time constant for the electrochemical experiment
w	angular frequency of the modulating sine wave in AC polarography or angular velocity for the RDE

ABBREVIATIONS AND ACRONYMS

AC	Alternating Current
ASV	Adsorptive Stripping Voltammetry
CME	Chemically Modified Electrode
CV	Cyclic Voltammetry
DC	Direct Current
DPP	Differential Pulse Polarography
EC	Electrochemical Reaction with a Subsequent Chemical Reaction
EC′	Electrochemical Reaction with a Parallel Chemical Regeneration
EDTA	Ethylenediamine Tetraacetic Acid
FAD	Flavin Adenine Dinucleotide
GOD	Glucose Oxidase
HRP	Horseradish Peroxidase
LSV	Linear Sweep Voltammetry
NAD^+/NADH	Nicotinamide Adenine Dinucleotide
$NADP^+$/NADPH	Nicotinamide Adenine Dinucleotide Phosphate
RDE	Rotating Disc Electrode
SCE	Saturated Calomel Electrode
SWV	Square-wave Voltammetry
TCNQ	Tetracyanoquinodimethane
TTF	Tetrathiafulvalene
UME	Ultramicroelectrode

Kinetic methods for analytical applications can be divided into noncatalytic and catalytic methods. Enzyme kinetic determinations are a special type of catalytic methods. Enzymatic reactions are used analytically to determine enzyme activities – for instance in the diagnosis of diseases, substrate concentrations in food industry or medicine and concentrations of effectors – for example in trace analysis. Due to the high selectivity of enzymatic analysis the importance of this method in various fields is growing rapidly. The widest use is observed in clinical chemistry and in food chemistry.

This article can only give a general survey of the great potential of enzymatic analysis, with references to more detailed literature.

Enzymatic reactions are characterized by some special features, explained after the introduction. The theoretical background for kinetic determination is the comprehension of the principles on enzymatic kinetics. In section 3 the simplest mechanism, outlined by Michaelis and Menten and several transformations of this equation will be described. In this section two kinetic parameters, enzyme activity and the Michaelis constant, will be introduced. Section 4 deals with substances, so called effectors, influencing the rate of an enzymatic reaction. Simple mechanisms of these effectors will be shown. The different methods for determination of substrates, enzymes and effectors, illustrated by many examples, are represented in section 5. While substrate concentrations can be determined using both ways, equilibrium or kinetic methods, the determination of enzymes and effectors can only be performed by kinetic approaches. In the last two sections the application of immobilized enzymes in flow systems and biosensor development will be shown.

1 INTRODUCTION

Kinetic methods are useful tools in analytical chemistry. The use of enzymes in kinetic-based determinations is widely applied for the analysis of many substances, for instance in medicine or the food industry, for the analysis of enzymes, especially enzyme activities in clinical diagnostics, and for the determination of inhibitors or activators of enzymes, i.e. trace analysis. The enzymatic analysis method combines the exceptional selectivity with high sensitivity. This article can only attempt a general survey of the enormous potential of the enzymatic analysis, with references to more detailed books or reviews.

At the beginning of this article the special features of enzymatic reactions are characterized and the theoretical background for the application of enzymatic catalysis, the comprehension of the principles on enzymatic kinetics, is described. The rate of the enzymatic reaction can be either increased or decreased by the effect of some substances known as activators or inhibitors, respectively. Simple mechanisms of the effectors are explained in section 4. Examples of the analytical application of enzymatic catalysis for the determination of substrates, enzymes and effectors are given. The use of immobilized enzymes in flow systems and biosensors is presented in the last, but not less interesting, two sections.

2 FEATURES OF ENZYMATIC REACTIONS

All enzymes are proteins produced by living cells that catalyze specific reactions with a high degree of efficiency. In the following the special features of enzymes will be represented, including some relevant information for their analytical uses.

2.1 High Specificity of Enzymes

Enzymes are very highly specific in their choice of substrate. Think of the 'key-lock' theory by Fischer or the 'induced fit' hypothesis, suggested by Koshland. Therefore, enzymes are unique analytical reagents. The ideal enzyme for analytical purposes would catalyze only one chemical reaction.

2.2 Temperature

Most enzymatic reactions are carried out within the physiological temperature range of 25–37 °C. As is known from other chemical reactions, there is an increase in reaction rate with temperature. In view of the fact that the enzyme is a protein, it becomes denatured above about 50 °C. Figure 1 shows a typical curve for the dependence of enzymatic activity on temperature. The optimum operating temperature differs from one enzyme to another. For enzymatic reactions it is very important to control the temperature during the measurement. Enzymes should be stored at 4 °C or less, since they can lose activity when stored at room temperature. Many producers of enzyme preparations use some substances to stabilize the preparations, but for some analytical purposes (see section 5.3) these substances can disturb the detection, for example the detection of inhibitors.

2.3 pH Value

Most enzymes are very sensitive to changes in pH. The effect of pH is due to an alteration in the conformation

Figure 1 Effect of temperature on the activity of a typical enzyme.

Figure 2 Effect of pH on the activity of a typical enzyme.

of the protein structure or the ionization of the active site of the enzyme or substrate. As seen in Figure 2 there is an optimum in pH value (generally in the pH range of 5–7). Therefore it is very important to keep the pH value constant during the measurement. The use of buffer is advisable. Extreme pH value leads also to denaturation of the protein. The proper choice of pH is especially important in enzyme assays with enzyme-coupled systems, because there can be different pH optima for the coupled enzymes.

2.4 Cofactors

Many enzymes need the presence of a nonprotein component (molecular mass generally between 10^2–10^3 g mol^{-1}), called cofactors, for catalytic activity. In this case, the inactive protein component is termed *apoenzyme* and the active enzyme, including cofactor, the *holoenzyme*. If the cofactor is an organic molecule it is called *coenzyme*. For analytical purposes, e.g. in photometric analysis, the coenzyme nicotinamide adenine dinucleotide (NAD) is widely used (see section 5.1). Other cofactors may be metal ions, e.g. zinc or iron ions. Their analytical importance is given in section 5.3.

2.5 Ionic Strength

Enzymatic reaction rates can be changed by the presence of some salts. The addition of small amounts of neutral salts may increase the solubility of a protein. Salts can cause changes in ionization of amino acid side chains. Therefore the choice of buffer recipe for any given pH is very important for the reaction rate and the mechanism of an enzymatic reaction.

3 REACTION MECHANISM AND KINETIC EQUATIONS

The following kinetic considerations are restricted to the classical approach by Michaelis and Menten. Deviations

from the hyperbolic dependence of the reaction rate on the substrate concentration will not be represented. Furthermore, in most cases only single substrate reactions are significant for the analytical application of enzymes.

3.1 Michaelis–Menten Equation

In the early 1900s two biochemists, Michaelis and Menten worked out a theory for the kinetic analysis of enzyme-catalyzed reactions. The simplified mechanism can be written as Equation (1):

$$\mathrm{E} + \mathrm{S} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \{\mathrm{ES}\} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \mathrm{P} + \mathrm{E} \tag{1}$$

where E is the enzyme, S the substrate, {ES} the intermediate enzyme–substrate complex and P the product(s). The k's are the rate constants. The substrate concentration is much larger than the enzyme concentration so that the formation of {ES} does not alter the substrate concentration. This reaction scheme has been treated both as pre-equilibrium[1] and as a steady-state case.[2] Then, the Michaelis–Menten equation becomes Equation (2):

$$-\frac{\mathrm{d[S]}}{\mathrm{d}t} = \frac{k_2[\mathrm{S}][\mathrm{E}]_0}{K_\mathrm{m} + [\mathrm{S}]} \tag{2}$$

K_m is the Michaelis constant, [S] the substrate concentration and $[\mathrm{E}]_0$ the total concentration of enzyme present. This expression shows the relationship between reaction rate and concentration of both substrate and enzyme. Equation (2) is the base of determination of substrate concentrations and enzyme activities.

Further on, we know that when the substrate concentration is very high, all the enzyme is present as the enzyme–substrate complex and the maximum rate v_max is reached (enzyme saturation). Under these conditions we have Equation (3):

$$v_\mathrm{max} = k_2[\mathrm{E}]_0 \tag{3}$$

We can substitute v_max in Equation (2) and get Equation (4):

$$-\frac{\mathrm{d[S]}}{\mathrm{d}t} = \frac{\mathrm{d[P]}}{\mathrm{d}t} = \frac{v_\mathrm{max}[\mathrm{S}]}{K_\mathrm{m} + [\mathrm{S}]} = \mathrm{v} \tag{4}$$

Equations (2) and (4) are only precisely valid in the case of the initial reaction rate v_0 (Equation 5):

$$v_0 = \frac{v_\mathrm{max}[\mathrm{S}]_0}{K_\mathrm{m} + [\mathrm{S}]_0} \tag{5}$$

For determinations of substrate concentration and enzyme activities we have to discuss two experimental possibilities:

1. $[\mathrm{S}] \gg K_\mathrm{m}$, thus the initial reaction rate v_0 is directly proportional to the enzyme concentration (Equation 6):

$$v_0 = \frac{k_2[\mathrm{S}]_0[\mathrm{E}]_0}{[\mathrm{S}]_0} = k_2[\mathrm{E}]_0 \tag{6}$$

   Since $v_\mathrm{max} = k_2\,[\mathrm{E}]_0$, this attempt is commonly called saturation conditions.
2. $[\mathrm{S}] \ll K_\mathrm{m}$, thus the initial reaction rate v_0 is directly proportional to the substrate concentration, assuming the determination has been carried out under constant enzyme condition ($v_\mathrm{max}/K_\mathrm{m} = \text{constant}$) (Equation 7):

$$v_0 = \frac{k_2[\mathrm{S}]_0[\mathrm{E}]_0}{K_\mathrm{m}} = \frac{v_\mathrm{max}}{K_\mathrm{m}}[\mathrm{S}]_0 \tag{7}$$

When the rate of an enzymatic reaction v is plotted against the substrate concentration [S] a hyperbolic curve is obtained (see Figure 3). Enzyme-catalyzed reactions show a first-order dependence of the reaction rate at low concentrations of substrate and as the substrate concentration rises, the reaction rate approaches a maximum rate v_max, the enzyme saturation. This is the region of zero-order kinetics. At intermediate substrate concentrations, the relationship between the reaction rate and the substrate concentration follows neither first-order nor zero-order kinetics.

3.2 Integrated Michaelis–Menten Equation

Mentioned in section 3.1, the Michaelis–Menten equation is only precisely valid in the case of the initial reaction rate v_0, i.e. when the substrate concentration $[\mathrm{S}] = [\mathrm{S}]_0$, or when less than 5% of [S] is converted to product P.[3] Under many experimental conditions it

Figure 3 Reaction rate plotted against substrate concentration for an enzyme-catalyzed reaction.

may not be feasible to restrict the reaction extent to 5% or less. In contrast to this, the integrated form of the Michaelis–Menten equation is valid over the entire course of the reaction. This we can write as Equation (8):

$$[S] = [S]_0 - [P] \tag{8}$$

[P] and [S] are the product or substrate concentration at time t.

Insertion of Equation (8) into Equation (4) leads to Equation (9):

$$v = \frac{d[P]}{dt} = \frac{v_{max}\left([S]_0 - [P]\right)}{[S]_0 - [P] + K_m} \tag{9}$$

Integration of Equation (9) between time $t = 0$ and any time t and between the corresponding two product concentrations 0 and [P] leads to Equation (10):

$$t = \frac{K_m}{v_{max}} \ln \frac{[S]_0}{[S]_0 - [P]} + \frac{[P]}{v_{max}} \tag{10}$$

Equation (10) presents the relationship between product concentration [P] and time t. Moreover, Equation (10) can be rearranged to give Equation (11):

$$t = \frac{K_m}{v_{max}} \ln \frac{[S]_0}{[S]} + \frac{[S]_0 - [S]}{v_{max}} \tag{11}$$

The application of Equation (10) for the determination of K_m and v_{max} (or the enzyme activity) is described in section 3.4.

3.3 Michaelis Constant and Enzyme Activity

The Michaelis constant, K_m, is defined as the substrate concentration at half the maximum reaction rate (Equation 12):

$$\text{when} \quad K_m = [S] \quad v = \frac{[S]v_{max}}{2[S]} = \frac{v_{max}}{2} \tag{12}$$

Thus K_m will have the same units as the substrate concentration. Using the two methods for treatment of enzyme-catalyzed reaction Equation (1), one can obtain Equations (14) and (16):

1. Michaelis–Menten assumption of equilibrium between substrate, enzyme and substrate–enzyme complex (pre-equilibrium or rapid equilibrium), $k_2 \ll k_{-1}$, Equation (13):

$$E + S \overset{K_s}{\rightleftharpoons} \{ES\} \xrightarrow{k_2} P + E \tag{13}$$

$$K_m^{I} = K_s = \frac{k_{-1}}{k_1} \tag{14}$$

K_s = dissociation constant for the enzyme–substrate complex

2. For Equation (15):

$$E + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \{ES\} \xrightarrow{k_2} P + E \tag{15}$$

Briggs–Haldane steady-state assumption, Equation (16):

$$K_m^{II} = \frac{k_{-1} + k_2}{k_1} \tag{16}$$

The Briggs–Haldane assumption is the more general one, eliminating the requirement for the enzyme–substrate complex to be in equilibrium with free enzyme and free substrate. Thus, K_m is a dynamic or pseudo-equilibrium constant. K_m is a constant for a given substrate under well-defined experimental conditions such as temperature, buffer, pH and ionic strength. It represents the affinity between the substrate and the enzyme. A small value of K_m means a high affinity between substrate and enzyme and the enzyme becomes saturated at small concentrations of substrate. Michaelis constants for enzyme usually range from 10^{-2} to 10^{-5} mol L^{-1}. For enzymatic analysis methods a small value of K_m results in a very limited linear concentration range in calibration graphs based on initial reaction rate as a function of substrate concentration. If we know K_m, we can adjust the experimental conditions for determining substrate concentration or enzyme activity (see section 3.1). The activity of an enzyme preparation varies from one source to another, since the purification of the enzyme is in general not complete. Because of this, in most preparations the actual molar concentration of enzyme is unknown, and therefore the quantity generally used to express the enzyme activity is the *unit*, defined in terms of reaction rate.

One international unit (U) of enzyme is defined as that amount catalyzing the conversion of micromole substrate to product in 1 minute under optimal conditions.

The declaration of the optimal conditions has to include the temperature (usually 25 or 30 °C), pH value and buffer system. For determining the enzyme activity the substrate concentration should be sufficient for saturation. The Nomenclature Commission of the International Union of Biochemistry has recommended the use of the *katal* (kat), which differs from the definition of the unit through the declaration of 1 mole substrate and time of 1 second:

$$1\,\text{kat} = 6 \times 10^7\,\text{U}$$

The *specific activity* of an enzyme preparation is the number of units per mg protein or in the case of solution or suspension one can declare the number of units per

milliliter. If the molecular mass of an enzyme is known it is possible to express the *molecular activity* in units per μmol enzyme.

In Palmer[4] one can also find the terms: *turnover number* k_{cat} and *catalytic efficiency* k_{cat}/K_m. The constant k_{cat} is defined in Equation (17):

$$k_{cat} = \frac{v_{max}}{[E]_0} \tag{17}$$

If the enzyme concentration is known the ratio k_{cat}/K_m is a good measure for catalytic efficiency of an enzyme.

3.4 Determination of Kinetic Parameters

The determination of the kinetic parameters v_{max} and K_m can be carried out by measuring the initial reaction rate as the substrate concentration is varied. If experimentally possible, the substrate concentration should be varied in the range from $K_m/10$ to 10 K_m. In the literature there are some linearization procedures (see Figure 4):

3.4.1 The Lineweaver–Burk Plot

The linearization of the Michaelis–Menten equation Equation (5) by Lineweaver and Burk (Figure 4a) is the most widely and traditionally used method. It is a double reciprocal plot (Equation 18):

$$\frac{1}{v_0} = \frac{K_m}{v_{max}}\frac{1}{[S]_0} + \frac{1}{v_{max}} \tag{18}$$

From the slope (K_m/v_{max}) or the intercept on the ordinate ($1/v_{max}$) or the intercept on the abscissa ($-1/K_m$) one can obtain the two kinetic parameters. But such a double-reciprocal method has a strong distorting effect on the data.

Figure 4 Transformations of the Michaelis–Menten equation to determine v_{max} and K_m. (a) Lineweaver–Burk plot; (b) Hanes plot; (c) Eadie–Hofstee plot.

3.4.2 The Hanes Plot

The plot $[S]_0/v_0$ versus $[S]_0$ due to Hanes and Woolf (Figure 4b) is much better with regard to this effect. The data are more evenly weighted over the whole concentration range. Equation (18) may be rearranged to give Equation (19):

$$\frac{[S]_0}{v_0} = \frac{1}{v_{max}}[S]_0 + \frac{K_m}{v_{max}} \tag{19}$$

From this linear plot the parameters K_m and v_{max} can be calculated.

3.4.3 The Eadie–Hofstee Plot

The Eadie–Hofstee plot (Figure 4c) is the straight line graph v_0 versus $v_0/[S]_0$, Equation (20):

$$v_0 = -K_m\frac{v_0}{[S]_0} + v_{max} \tag{20}$$

Both plots (Eadie–Hofstee plot and Hanes plot) are less frequently used, but they are better suited for kinetic determination than the Lineweaver–Burk plot.

3.4.4 Integrated Michaelis–Menten Equation

All above-mentioned methods require the measurement under initial conditions. If it is not possible to fulfill this requirement – for example, it may be difficult to determine very low concentrations of product – one can use the integrated Michaelis–Menten equation (see section 3.2) for the determination of v_{max} and K_m. The linear transformation of Equation (10) gives Equation (21):

$$\frac{t}{[P]} = \frac{K_m}{v_{max}}\frac{1}{[P]}\ln\frac{[S]_0}{[S]_0 - [P]} + \frac{1}{v_{max}} \tag{21}$$

The Michaelis constant and maximum rate can be determined by measuring the concentration of product several times during the reaction and plotting the respective values as shown in Figure 5.

Figure 5 Plot of integrated Michaelis–Menten equation.

4 MODIFYING THE KINETIC BY EFFECTORS

The rate of the enzymatic reaction can be either increased or decreased by effectors. While activators accelerate the enzymatic reaction, inhibitors reduce the rate of the enzymatic reaction. For this reason all enzymatic analyses of effectors involve the determination of reaction rates (different kinetic methods are described in section 5 or in Pérez-Bendito and Silva[5]).

4.1 Activators

An activator increases the catalytic effectiveness or the activator transforms the inactive apoenzyme (see section 2.4) to the active holoenzyme. Various substances can activate the same enzyme. In consequence, there is a lack of specificity for determination of individual ions.

The course of the initial rate in the presence of an activator is similar to that of substrate concentration, discussed in section 3.1. At low activator concentration one can find that the initial rate is directly proportional to the concentration of the activator. But at higher concentrations the enzyme is maximally activated (similar to the enzyme saturation at high substrate concentrations) and the initial rate becomes independent of the concentration of the activator. Consequently the determination of effectors has to be carried out at low levels of activator concentrations. Examples for the analytical application, e.g. the determination of metallic ions, are given in section 5.3.

4.2 Inhibitors

Inhibitors are substances which cause a decrease in the rate of a catalytic reaction. The enzyme inhibition can be either reversible or irreversible. The characteristic of the reversible inhibition is the equilibrium between enzyme and inhibitor. In contrast, the irreversible inhibitor binds covalently to the enzyme. Seen from Figure 6, the enzymatic reaction rate can be influenced by several substances. We distinguish:

Figure 6 Schematic representation of the various forms of inhibition.

- substrate inhibition
- product inhibition
- competitive inhibition (formation of enzyme–inhibitor complex EI)
- uncompetitive inhibition (formation of enzyme–inhibitor–substrate complex EIS)
- noncompetitive inhibition (equal affinity of formation of EI and EIS).

4.2.1 Competitive Inhibition

The inhibitor competes with substrate (or coenzyme) for the active centre of the enzyme. Since the inhibitor forms the enzyme-inhibitor complex, the proportion of free enzyme will be reduced and the rate of the enzymatic reaction decreases. Hence, the competitive inhibition can be made ineffective by an excess of substrate. In most cases we find that the chemical structure of the substrate is similar to that of the competitive inhibitor. Figure 7(a) shows the Lineweaver–Burk plot of the competitive inhibited enzyme reactions. The curves increase in slope (increase in K_m), while the intercept on the $1/v_0$ axis remains constant. The maximum rate in the presence of a competitive inhibitor is always equal to v_{max} of the uninhibited reaction.

4.2.2 Uncompetitive Inhibition

The inhibitor binds only to the enzyme–substrate complex ES. Figure 7(b) shows the Lineweaver–Burk plot of the uncompetitive inhibited enzyme reaction. The uncompetitive inhibitor decreases v_{max} and K_m. The decrease of K_m means an apparent increase in the affinity of the enzyme for its substrate.

4.2.3 Noncompetitive Inhibition

The inhibitory mechanism, where the inhibitor binds with equal affinity to both the enzyme and the enzyme–substrate complex, is called noncompetitive

Figure 7 Lineweaver–Burk plots for (a) competitive inhibition; (b) uncompetitive inhibition; (c) noncompetitive inhibition.

inhibition. Noncompetitive inhibitors bind to the enzyme at a site that is distinct from the substrate binding site.[6]

Hence, this type of inhibition cannot be overcome by increasing the substrate concentration. Figure 7(c) illustrates that the noncompetitive inhibition leads to an apparent decreasing of v_{max}, while the Michaelis constant is not altered.

4.2.4 Substrate Inhibition

As represented in section 3.1, the initial rate of an enzyme reaction increases with increasing initial substrate concentration to a maximum value v_{max}. But in some cases we can find a decreased initial rate at high substrate concentrations, seen in Figure 8. There, an excess of substrate can inhibit its own conversion to product.

4.2.5 Product Inhibition

The product of some enzyme reaction can also be an inhibitor. The product may bind to the active site of the enzyme. Consequently the active site is blocked and cannot bind further substrate molecules. Thus, the rate of the enzyme reaction decreases.

Figure 8 Substrate inhibition.

The represented types of enzyme inhibition are not complete. More detailed information can be found in Segel.[7] Examples for analytical application are given in section 5.3.

5 ENZYMATIC DETERMINATIONS

The methods to be used in monitoring enzyme-catalyzed reactions are dictated by the chemistry and physical chemistry of the reaction. We can distinguish three classes:

- spectrophotometric
- electrochemical
- calorimetric.

In the following only some typical examples of the determination of substrates, enzymes and effectors, using different monitoring techniques, are represented. In the literature one enzyme plays an exceptional role – glucose oxidase (GOD) as analytical reagent is the most widely used enzyme.[8]

5.1 Determination of Substrates

The substrate determination can be carried out by both, equilibrium and kinetic approaches. The *equilibrium method*, also called *end-point method*, means the measurement of the total change, almost all of the substrate being converted to product. The analysis can be performed by measuring the appearance of product or the disappearance of substrate. To ensure rapid progress towards equilibrium, the concentration of the used enzyme should be high. Any other substances necessary for enzyme-catalyzed reaction, such as cofactors (coenzyme or metal ions), should be in excess, so that they do not limit the reaction. Because of the possible side reactions or instability of products or reactants, the enzyme reactions are often not stoichiometric with respect to the substrate concentration. Therefore the calibration curves must be prepared under the selected experimental conditions. There, the measured quantity is related to known concentrations of substrates.

The *kinetic determinations* of substrates should be carried out under conditions where the concentration of substrate is in the range to fulfill the first order circumstances ($[S]_0 \ll K_m$, see Equation (7) section 3.1). In Christian[9] one can find three forms:

- measure the time required for the reaction to convert a certain amount of substrate or form a certain amount of product
- measure the amount of substrate converted or product generated in a given time and
- continuous measurement of substrate or product concentration as a function of time, or initial slope method.

The initial slope method means that the change in some physicochemical parameters (absorption, pH or temperature), related to the change of concentration, are plotted as a function of time. Kinetic methods are generally more rapid than equilibrium methods, but also more sensitive to enzyme effectors.

Analytical applications of enzyme-catalyzed reactions for determining substrates are widely used in many fields. Table 1 gives some examples for applications in food industry, medicine and environmental analysis; further pertinent information can be found in Bergmeyer.[10]

As seen from Table 1, many reactions with dehydrogenases need the coenzyme NAD. The NADH and the oxidized form (NAD^+) differ in their ultraviolet absorption spectra. NAD does not adsorb photons in the 340 nm region of spectra, whereas its reduced form does.

Such differences in absorption spectra of products, substrates or other reactants are widely used in the

Table 1 Typical determinations of substrates using enzymes

Substrate	Enzyme	E.C. number	CAS registry number	Reaction	Examples for application
A Food industry					
ethanol	alcohol dehydrogenase	1.1.1.1	9031-72-5	ethanol + NAD^+ ⟶ acetaldehyde + NADH + H^+	alcoholic drinks
sucrose	invertase	3.2.1.26	9001-57-4	sucrose + H_2O ⟶ glucose + fructose	fruit juices, syrups
glutamic acid	glutamic dehydrogenase	1.4.1.3	9029-12-3	glutamate + NAD^+ + H_2O ⟶ 2-oxoglutarate + NADH + NH_4^+	spices, meat
ascorbic acid	ascorbatoxidase	1.10.3.3	9029-44-1	ascorbate + $\frac{1}{2}O_2$ ⟶ dehydroascorbate + H_2O	fruit juices, drinks, meat
sorbitol	sorbitol dehydrogenase	1.1.1.14	9028-21-1	sorbitol + NAD^+ ⟶ fructose + NADH + H^+	foodstuffs for diet, fruits
B Medicine					
cholesterol	cholesterol oxidase	1.1.3.6	9028-76-6	cholesterol + O_2 ⟶ 4-cholesten-3-one + H_2O_2	blood analysis of risk factors
glucose	GOD	1.1.3.4	9001-37-0	glucose + O_2 + H_2O ⟶ gluconic acid + H_2O_2	diagnosis of diabetes
	glucose dehydrogenase	1.1.1.47	9028-53-9	glucose + NAD^+ + H_2O ⟶ gluconic acid + NADH + H^+	
lactic acid	D-LDH	1.1.1.28	9028-36-8	(R)lactate + NAD^+ ⟶ pyruvate + NADH + H^+	sports medicine
uric acid	uricase	1.7.3.3	9002-12-4	urate + O_2 + $2H_2O$ ⟶ allantoin + CO_2 + H_2O_2	diagnosis of gout
penicillin	penicillinase	3.5.2.6	9001-74-5	penicillins + H_2O ⟶ penicilloic acid	diagnosis of allergy
C Environment					
phenol	tyrosinase	1.14.18.1	9002-10-2	phenol + $\frac{1}{2}O_2$ ⟶ *o*-benzochinone	drinking water, waste water
urea	urease	3.5.1.5	9002-13-5	urea + $2H_2O$ + H^+ ⟶ HCO_3^- + $2NH_4^+$	bathwater
nitrate	nitrate reductase	1.6.6.1	9013-03-0	nitrate + NADH + H^+ ⟶ nitrite + NAD^+ + H_2O	water

NADH, reduced form of nicotinamide adenine dinucleotide; LDH, lactate dehydrogenase.

spectrophotometric method to follow the progress of enzyme reactions.

As an example, the amount of NADH produced according to Equation (22) is a measure of the amount of acetaldehyde present in wine or beer.[11]

$$\text{Acetaldehyde} + NAD^+ + H_2O \xrightarrow{\text{Al-DH}} \text{acetic acid} + NADH + H^+ \quad (22)$$

(Al-DH = aldehyde dehydrogenase, E.C. 1.2.1.3, 9028-86-8)

Moreover, NADH is used as a coupling agent. Two or more reactions occur in sequence. At the end of such a sequence, NAD^+ is generated or consumed. For example, the determination of creatinine or creatine is represented by Equation (23–26):

$$\text{Creatinine} + H_2O \xrightarrow{\text{CAH}} \text{creatine} \quad (23)$$

$$\text{Creatine} + ATP \xrightarrow{\text{CK}} \text{creatine phosphate} + ADP \quad (24)$$

$$ADP + \text{phosphoenolpyruvate} \xrightarrow{\text{PK}} ATP + \text{pyruvate} \quad (25)$$

$$\text{Pyruvate} + NADH + H^+ \xrightarrow{\text{LDH}} \text{L-lactate} + NAD^+ \quad (26)$$

The amount of NADH consumed is stoichiometric with the amount of creatine or creatinine.[12]

(CAH creatinine amidohydrolase, E.C. 3.5.2.10, 9025-13-2
CK creatinine kinase, E.C. 2.7.3.2, 9001-15-4
PK pyruvate kinase, E.C. 2.7.1.40, 9001-59-6
LDH E.C. 1.1.1.27, 9001-60-9)
ADP adenosine diphosphate
ATP adenosine triphosphate

The coupling of enzyme-catalyzed reactions with further reactions is commonly applied in enzymatic analysis, chiefly by using spectrophotometric or electrochemical methods. In contrast, the *calorimetric determination (enthalpimetry)* of substrate is much more general.[13] Each enzyme reaction with a defined product can be used. There is no demand for colored products or electrochemically active reactants. The measured heat is proportional to the substrate concentration.

Furthermore, Table 1 shows that the reaction of oxidases consumes oxygen. That makes them accessible to an *electrochemical method*, the amperometric detection. For the *amperometric determination* one can also use the production of hydrogen peroxide, Equation (27):

$$\text{glucose} + O_2 + H_2O \xrightarrow{\text{GOD}} \text{gluconic acid} + H_2O_2 \quad (27)$$

The hydrogen peroxide is electrochemically oxidized at the platinum cathode, Equation (28):

$$H_2O_2 \longrightarrow O_2 + 2H^+ + 2e^- \quad (28)$$

The current obtained is proportional to the glucose concentration (principle of Clark oxygen electrode).

The substrate concentration of such an oxidase-catalyzed reaction (Equation 27) can also be measured with an *iodide-selective electrode*[14], Equation (29):

$$H_2O_2 + 2I^- + 2H^+ \xrightarrow{\text{Mo(VI)}} I_2 + 2H_2O \quad (29)$$

The decrease in iodide concentration is proportional to the substrate concentration, for instance glucose.

In H_2O_2-generating systems, substrate concentrations can also be determined by using *indicator reactions*.[15] One example is the determination of glucose with indicator reactions based on the peroxidase (E.C. 1.11.1.7, 9003-99-0) catalyzed oxidation of single chromogen (Equation 30).

An interesting way to increase the sensitivity of enzymatic substrate determinations is *amplification by cycling of enzyme-catalyzed reactions*. The principle based on the following scheme:

The substrate to be determined is converted by an initial enzyme to a product. This product is the substrate of a second enzyme, which regenerates the substrate. Therefore it can be converted by the first enzyme again and thus the cycle is reinitiated.

A typical example is the determination of NADP by a cycling of NADPH between two enzyme reactions.[16]

5.2 Determination of Enzymes

Since enzymes are catalysts, affecting the rate of the reaction, not the equilibrium, their activity must be

measured by a *kinetic* method. The kinetic determination of enzymes should be carried out under conditions where the substrate concentration is in excess and all other substances which influence the rate of reaction are present in fixed and non-limiting concentrations. Then the value of K_m can be neglected and the rate of the enzyme reaction depends only on the enzyme concentration (zero order conditions, $[S]_0 \gg K_m$ see Equation (6) section 3.1). The three possible forms of determination are identical to the *kinetic* determination of substrates (see section 5.1). Because of the influence on the enzyme activity (see section 2), the pH value and the temperature have to keep constant during the measurement.

Enzyme determinations are chiefly applied in clinical diagnostics, food industry and monitoring biotechnological processes. Table 2 shows a selection of interesting enzymes; further information is found in Bergmeyer.[10]

As seen in the Table 2, *spectrophotometric monitoring* of NADH consumption as a function of time can be used to determine the enzyme activity of various enzymes.

The determination of amylase activity by measuring the produced reducing sugar as a function of time is an example of the application of the *colorimetric method*. An alkaline solution of 3,5-dinitrosalicylic acid and K-Na-tartrate is used as a chromogenic reagent.[17] Another, even more simple, case of *colorimetric method* is the determination of the AP activity. There the formation of the yellow *p*-nitrophenol under alkaline conditions is measured.

Furthermore the *pH-stat method* is used to determine enzyme activities. Monitoring enzyme reaction by pH-stat method means that the pH is maintained at constant value by frequent addition of alkali. The rate at which the base is added is proportional to the enzyme activity. The determination of lipase activity in serum (Equation 31) is a typical example.[18]

$$\text{Triglyceride} + H_2O \xrightarrow{\text{lipase}} \text{diglyceride} + \text{fatty acid} \quad (31)$$

Table 2 Typical examples for enzyme determinations

Enzyme	E.C. number	CAS registry number	Reaction	Application
glutamic-oxaloacetic transaminase (GOT)	2.6.1.1	9000-97-9	asparate + α-ketoglutarate $\xrightarrow{\text{GOT}}$ glutamate + oxaloacetate oxaloacetate + NADH + H^+ $\xrightarrow{\text{MDH}}$ malate + NAD^+ (MDH malate dehydrogenase, E.C. 1.1.1.37, 9001-64-3)	clinical diagnostics, fresh meat control
glutamic-pyruvic transaminase (GTP)	2.6.1.2	9000-86-6	L-alanin + α-ketoglutarate $\xrightarrow{\text{GPT}}$ glutamate + pyruvate pyruvate + NADH + H^+ $\xrightarrow{\text{LDH}}$ lactate + NAD^+	clinical diagnostics (liver diagnostic, bilious attack)
LDH	1.1.1.27	9001-60-9	pyruvate + NADH + H^+ $\xrightarrow{\text{LDH}}$ lactate + NAD^+	clinical diagnostics (cardiac infarction)
CK	2.7.3.2	9001-15-4	creatinine phosphate + ADP $\xrightarrow{\text{CK}}$ creatine + ATP	clinical diagnostics (cardiac infarction)
alkaline phosphatatse	3.1.3.1	9001-78-9	*p*-nitrophenylphosphate + H_2O $\xrightarrow{\text{AP}}$ *p*-nitrophenol + phosphate	food industry (milk products)
α-amylase	3.2.1.1	9000-90-2	polysaccharide containing alpha-(1-4)-linked glucose units + H_2O $\longrightarrow$ maltooligosaccharides	biotechnological processes
lipase	3.1.1.3	9001-62-1	triglyceride + H_2O $\xrightarrow{\text{lipase}}$ diglyceride + fatty acid	biotechnological processes detergent industry
catalase	1.11.1.6	9001-05-2	$H_2O_2 \longrightarrow H_2O + O_2$	food stuffs
alanine aminopeptidase	3.4.11.2	9054-63-1	aminoacyl-peptide + H_2O $\longrightarrow$ amino acid + oligopeptide	waste water
peroxidase	1.11.1.7	9003-99-0	donor + $H_2O_2 \longrightarrow$ oxidized donor + H_2O	food stuffs

AP, alkaline phosphatase.

The produced fatty acid is neutralized by counter titration with NaOH. Normally olive oil is used as the substrate. More examples for enzyme determinations and automated pH-stat systems can be found in Gul et al.[19]

Among the pH-stat systems, other *electrochemical methods* such as *conductometry* (change in overall ionic mobility is measured as a function of time), *amperometry* (O_2 consumption or H_2O_2 production is measured as a function of time) or *ion-sensitive electrodes* (see section 5.1) are also usable.

The *calorimetric determination* of invertase activity is described.[20] The sucrose hydrolysis shown in Equation (32) was performed in an isoperibolic calorimeter (invertase, E.C. 3.2.1.26, 9001-57-4). The kinetic evaluation of the calorimetric curves qualified to determine the enzymatic activity.

$$\text{sucrose} + H_2O \xrightarrow{\text{invertase}} \text{glucose} + \text{fructose} \quad (32)$$

Finally, *electrophoresis* is an important method for determining the catalytic activity of nucleases.[21]

5.3 Determinations of Effectors

The rate of the enzyme reaction can be influenced by various substances (see section 4). This characteristic feature of enzyme reactions can be used for analytical purposes, the determination of *activators* and the determination of *inhibitors*. These methods are especially important in trace metal determinations, since in most cases only a single oxidation state of metal is determined. The enzymatic analysis based on activator effects is not as frequently used as the determination based on inhibitor effects. Because effectors influence the kinetic of the enzyme reaction, their determination requires the monitoring of enzyme reactions as a function of time, i.e. kinetic determinations.

5.3.1 Activators

Many enzymes require for their catalytic activity *cofactors* (see section 4.1) or the 'true substrate' (SA), where A is generally a metal ion.[22] For example, reactions involving ATP require Mg^{2+} ions to form $MgATP^{2-}$ ($A = Mg^{2+}$).

For instance, the amounts of magnesium can be determined according to Equation (33):

$$\text{luciferin} + O_2 + \text{ATP} \xrightarrow[Mg^{2+}]{\text{luciferase}} \text{oxyluciferin} + \text{ADP} + PO_4^{3-} \quad (33)$$

The formation of oxyluciferin is combined with green *chemiluminescence*. Trace amounts of magnesium (ppb levels) can be determined.[23]

Other inorganic substances combine with the enzyme at a specific activator site. This activation may be essential or nonessential. Table 3 shows some examples of activation by inorganic substances. Pertinent information on the requirement or effectiveness of some substances for the catalytic activity of multitude of enzymes can be found in Schomburg and Salzmann.[24] These details are important for the application of activator effects for analytical purposes.

The experimental procedure of trace element analysis, using *metallo-enzymes* (specific metal ions are located at the active centers of the enzyme) is characterized by the removal of the metal ion from the holoenzyme (see section 4.1) by treatment with chelating agents (for instance EDTA). The resultant *apoenzyme* is catalytically inactive. The activator assay consists of the respective apoenzyme, its natural substrate, and a sample containing the metal ion. Then the restoration of enzyme activity is proportional to the amount of metal ion in the sample. In this way trace amounts of metal ions can be determined. An example is the determination of zinc ions by using AP (Equation 34):

Table 3 Examples for activation of enzymes by inorganic substances

Enzyme	E.C. number	CAS number	Activators	Ref.
arginase	3.5.3.1	9000-96-8	Mn^{2+}	25
citrate lyase	4.1.3.6	9012-83-3	Mg^{2+}, Mn^{2+}, Fe^{2+}, Zn^{2+}	25
enolase	4.2.1.11	9014-08-8	Mg^{2+}	25
cytochrome oxidase	1.9.3.1	9001-16-5	Cu^{2+}	26
carboxypeptidase A	3.4.17.1	11075-17-5	Zn^{2+}	26
creatinine kinase	2.7.3.2	9001-15-4	Mg^{2+}, Mn^{2+}	26
glycerokinase	2.7.1.30	9030-66-4	Mg^{2+}	26
isocitrate dehydrogenase	1.1.1.41	9001-58-5	Mn^{2+}, Zn^{2+}, Co^{2+}	27
phosphofructokinase	2.27.1.11	9001-80-3	K^+	27
AP	3.1.3.1	9001-78-9	Zn^{2+}, Mg^{2+}, Mn^{2+}, Co^{2+}	25 28
collagenase	3.4.24.3	9001-12-1	Ca^{2+}	25
luciferase	1.13.12.7	61970-00-1	Mg^{2+}	27

$$\text{4-nitrophenyl phosphate} + H_2O \xrightarrow{AP} \text{4-nitrophenol} + \text{phosphate} \quad (34)$$

The enzyme activity is determined by measuring the rate of release of 4-nitrophenolate ion (alkaline pH) at 410 nm in a recording spectrometer. The method is so sensitive that 0.5 ng zinc can be determined in small volumes (0.5 µl) of plasma.[29]

Many enzymes require for their catalytic activity a specific *coenzyme* (see Table 4). At low concentrations of enzyme the degree of activation of such an enzyme is proportional to the concentration of coenzyme. That is in contrast with the assay for determining substrate concentrations (see section 5.1), where the coenzyme should be in excess.

For instance, ATP, an important intermediate in energy metabolism, can be determined by the following reaction scheme (Equations 35 and 36):

$$\text{ATP} + \text{glucose} \xrightarrow{HK} \text{glucose-6-phosphate} + \text{ADP} \quad (35)$$

Table 4 Some examples of coenzymes

Coenzyme	Abbreviation	Apoenzyme	Function
adenosine triphosphate	ATP	kinases, transferases	transphosphorylation
coenzyme A	CoA	acyltransferases, thioligases	acyl group transfer
flavine adenine dinucleotide	FAD	oxidases	proton transfer
nicotinamide adenine dinucleotide	NAD	dehydrogenases	proton transfer
pyridoxal phosphate	PAL	transaminases	amino group transfer

$$\text{glucose-6-phosphate} + NADP^+ \xrightarrow{G6PDH} \text{glucono-1,5-lactone 6-phosphate} + NADPH \quad (36)$$

(HK Hexokinase, E.C. 2.7.1.1, 9001-51-8
G6PDH glucose 6-phosphate dehydrogenase, E.C. 1.1.1.49, 9001-40-5)

The reaction can be monitored by the formation of NADPH spectrophotometrically at 340 nm.

5.3.2 *Inhibitors*

In the literature one can find a variety of enzyme inhibitors. Table 5 shows a selection of well-known inorganic and organic inhibitors. The relative effect on enzyme activity of different substances is characterized by the IC_{50} value. The IC_{50} value is the inhibitor concentration giving 50% inhibition.[30] Several analytical methods have been developed based on the inhibition of enzyme reactions.

As seen from Table 5, one enzyme often has various inhibitors. Therefore, investigations of inhibitor effects are not as practicable for single-component analysis as for determination of summary or group specific parameters. An example is the screening of pollutants in waste water. Furthermore, enzyme inhibition tests are suitable to preselect polluted samples.

In the following some examples for analytical application (see also sections 6 and 7) are represented. There is a variety of methods for determination of inhibitors, dictated by the physicochemistry of the enzyme reaction to be monitored.

The urease-catalyzed urea hydrolysis can be inhibited by various metal ions (see Table 5). The inhibitor effect is used for the screening of heavy metals in water. An example is the *microtiter-plate urease inhibition assay*

Table 5 Some examples for inhibitors

Enzyme	Inhibitor	E.C. number	CAS number	Ref.
delta-aminolevalinic dehydratase	Pb^{2+}	4.2.1.24	9036-37-7	31 Vol. IV
urease	Cd^{2+}, Hg^{2+}, Cu^{2+}, Zn^{2+}	3.5.1.5	9002-13-5	32
lipase	Fe^{2+}, Zn^{2+}, Co^{2+}	3.1.1.3	9001-62-1	33
arylsulfatase	phosphate, sulfate	3.1.6.1	9016-17-5	33
catalase	ascorbic acid	1.11.1.6	9001-05-2	32
cholinesterase	pesticides	3.1.1.7	9000-81-1	32
beta-galoctosidase	organic SH-compounds	3.2.1.23	9031-11-2	33
dihydrofolate reductase	methotrexate (MTX)	1.5.1.3	9002-03-3	31 Vol. XII
invertase	Ag^{+}, Hg^{2+}	3.2.1.26	9001-57-4	32
phosphoenolpyruvate carboxylase	pesticide, Hg^{2+}, Co^{2+}, Pb^{2+}, Zn^{2+}, Cu^{2+}	4.1.1.31	9067-77-0	34
GOD	Ag^{+}, Hg^{2+}, Pb^{2+}	1.1.3.4	9001-37-0	32

based on the determination of the released ammonia with an indophenol reaction. Highest sensitivity was found for Hg^{2+} (detection limit of $0.05\,\mu g\,L^{-1}$).[35]

Pesticide pollution in water is a serious problem, especially for drinking water quality. The acetylcholinesterase (ACHE) inhibition test is a well-known method for the determination of organophosphorous acid esters and *N*-methyl carbamates. *Photometric* tests are widely used. The hydrolysis of acetylthiocholine by ACHE (E.C. 3.1.1.7, 9000-81-1) is measured (Equations 37 and 38):

$$\text{acetylthiocholine} + H_2O \xrightarrow{\text{ACHE}} \text{thiocholine} + CH_3COOH \quad (37)$$

$$\text{thiocholine} + \text{dithiobisnitrobenzoate} \longrightarrow \text{thionitrobenzoate (yellow dye)} \quad (38)$$

The entire inhibition effect, in comparison with the uninhibited ACHE, is given in paraoxon equivalent.[36]

This inhibition effect can also be measured by *amperometric* detection (Equations 39–41)

$$\text{acetylcholine} + H_2O \xrightarrow{\text{ACHE}} \text{choline} + CH_3COOH \quad (39)$$

$$\text{choline} + 2O_2 + H_2O \xrightarrow{\text{choline oxidase}} \text{betaine aldehyde} + 2H_2O_2 \quad (40)$$

$$H_2O_2 \xrightarrow{\text{anodic oxidation}} O_2 + 2e^- + 2H^+ \quad (41)$$

(choline oxidase, E.C. 1.1.3.17, 9028-67-5).

The inhibition of ACHE is proportional to pesticide concentration and measured through the decrease of the current.[37]

Inhibition studies are also suitable to distinguish between oxidation states of metals. As an example, *calorimetric investigations* of urease inhibition of heavy metals show that As(III)-ions inhibit the urea hydrolysis by competitive mechanism, while As(V)-ions do not inhibit the enzyme in the comparable concentration range.[38] For the evaluation of the potential of toxicological hazard the differentiation of arsenic content should be important.

6 IMMOBILIZED ENZYMES FOR DETERMINATIONS IN FLOW SYSTEMS

In analytical chemistry the use of immobilized enzymes is rapidly increasing. The term *immobilized enzymes* stands for a preparation in which an enzyme is confined or localized in a relatively well defined region. Enzymes may be immobilized by covalent bindings, by crosslinking, adsorption or entrapment within various matrices, for instance membranes or polymeric gels. Different techniques used for the immobilization of enzymes are described extensively.[39,40]

Enzyme immobilization is an economical requirement, since an immobilized enzyme can easily separate from the reaction solution and becomes therefore reusable. Besides, immobilization frequently leads to an improvement of thermal and/or chemical stability of enzyme preparation in comparison to the soluble or native enzyme. On the other hand, the immobilization often causes a reduction of catalytic activity. Immobilized enzyme systems always differ from the soluble counterparts by the K_m value or the optimal pH condition.

A further advantage of immobilization is the possibility to prepare *multienzyme systems*, where two or more enzymes immobilized on the same carrier. Immobilized multienzyme systems are suitable to catalyze sequential sets of reactions.

The application of immobilized enzymes in flow systems is a very convenient way for rapid and automated enzymatic determinations. The most common configurations in such flow systems are packed bed reactors or open-tube wall reactors.

In packed bed reactors especially covalent enzyme binding on controlled pore glass (CPG) or polymeric carrier is used. In open-tube reactors the enzymes are bounded to the inner surface of tubes. The sample-handling technique used in packed bed reactors and open-tube wall reactors is the flow injection analysis (FIA). FIA means short analysis times, and ease of automation. FIA is based on the injection of the liquid sample into a nonsegmented continuous buffer stream.[41] The injected sample forms a zone in the stream, which is then flowing into the enzyme reactor. There the enzyme reaction takes place and the resultant change in a physicochemical parameter (e.g. absorption, temperature, pH) is registered by the detector. Figure 9 shows a practicable arrangement of the flow system for enzymatic determinations in a simplified representation.

The detector signal during the passage of the sample (substrate zone) has the form of a peak. The analytical information is given by the peak height, the peak area or

Figure 9 Simplest arrangement of enzymatic flow system. P: pump; V: valve; ER: enzyme reactor; D: detector.

the width of the peak, which is analogous to the exploration in chromatographic measurements. The enzymatic flow systems are calibrated with standard solutions before their application. The operating conditions, as pH, buffer system or buffer flow stream have to be optimized. In FIA systems kinetic controlled reactions take place.

The arrangements of enzymatic flow injection systems vary with the analytical problem to be solved. A review of FIA techniques is given in Ružička and Hansen;[42] the authors introduced this method in the analytical chemistry. Multiline manifolds, combination of several enzyme reactors, enzyme reactors with multienzyme immobilization are described, also.

Enzymatic flow systems are suitable to determine substrates, coenzymes, inhibitors or enzyme activities, and for application such as on-line monitoring, control of biotechnological processes or medicine.

In the following some interesting examples of application of immobilized enzymes in flow systems are represented. The use of immobilized enzymes to construct biosensors, which can also incorporate in flow systems, is explained in section 7.

A FIA system for measuring of acetate, ethanol, glucose, L-lactate and pyruvate is developed by Schürgel and Rhee,[43] and described by Equations (42–46). Alcohol oxidase (AOD, E.C. 1.1.3.13, 9073-63-6), GOD (E.C. 1.1.3.4, 9001-37-0), LDH (E.C. 1.1.1.27, 9001-60-9), lactate monooxygenase (LMO, E.C. 1.13.12.4, 9028-72-2) and sarcosine oxidase (SOD, E.C. 1.5.3.1, 9029-22-5) were immobilized on VA-Epoxy-Biosynth E3 carrier. In that publication the influence of *metabolites* on enzyme based FIA is investigated. Three different detection methods are used. The oxygen consumption (Equations 42–44) is evaluated with an oxygen electrode, the peroxide production (Equation 46) is detected with the redox indicator 2,2′-azino-di(3-ethylbenzthiazoli-sulfonic acid-6) (ABTS), and the NADH reduction (Equation 45) is evaluated spectrophotometrically.

$$\text{ethanol} + O_2 \xrightarrow{\text{AOD}} \text{acetaldehyde} + H_2O_2 \quad (42)$$

$$\text{glucose} + O_2 \xrightarrow{\text{GOD}} \text{gluconic acid} + H_2O_2 \quad (43)$$

$$\text{L-lactate} + O_2 \xrightarrow{\text{LMO}} \text{acetate} + CO_2 + H_2O \quad (44)$$

$$\text{pyruvate} + \text{NADH} + H^+ \xrightarrow{\text{LDH}} \text{L-lactate} + \text{NAD}^+ \quad (45)$$

$$\text{sarcosine} + H_2O + O_2 \xrightarrow{\text{SOD}} \text{glycine} + \text{formaldehyde} + H_2O_2 \quad (46)$$

Since acetate is a competitive inhibitor of the reaction with SOD, the reduction of the reaction rate (Equation 46) is proportional to the concentration of acetate.

A recent trend in analytical chemistry is the miniaturization. As an example *capillary flow injection* (CFI) is combined with an immobilized enzyme reactor (open tubular capillary reactor). The glucose determination in juice and soft drinks has been described.[44]

Chloramine is used as bleaching and disinfecting agent or antiseptic. Its determination, based on an inhibition reaction, is discussed.[45] Chloramine is an *inhibitor* of peroxidase. The flow injection peroxidase reactor is made out of a steel tube in which the enzyme immobilizate (polymer carrier) is filled. A detection limit for chloramide of 26 μmol L^{-1} was obtained.

An automated system for *multichannel* FIA, in which up to six different analytes can be determined sequentially, is described.[46] The enzyme reactors are configured in parallel and only one fluorescence detector is necessary for the sequentially implemented determinations. Furthermore the FIA *stopped flow method* is used to control the analyte conversion and to optimize multistep enzymatic assays.

FIA technique in combination with immobilized enzymes is a powerful tool for on-line monitoring of cultivation processes. The concentrations of penicillin and glucose have been measured online during penicillin production by the filamentous fungus *Penicillium chrysogenum*.[47] In this publication a development of FIA, called *sequential injection analysis* (SIA), has been employed. SIA allows the determination of more than one component in the same manifold.

An example of the use of *coimmobilized enzymes* is given.[48] G6PDH and diaphorase (E.C. 1.6.99.1, 9001-68-7) are employed to enhance the sensitivity of NAD(P) coenzymes as on-line amplifiers on substrate recycling (see section 5.1) in a chemiluminometric flow injection system.

The combination of immobilized enzymes in flow systems with calorimetric detection is used in the *enzyme thermistor device* (ET).[49] The immobilized enzymes arranged in columns and the temperature is generally measured at the top of the column with a thermistor. As a result of the enzyme catalyzed reaction, a temperature peak can be detected. The height of the peak is proportional to the enthalpy change, corresponding to a definite substrate concentration. Normally, the ET device is calibrated with known concentrations of an analyte. With such an arrangement many substances can be determined.[50]

Another recently developed flow instrument is *bypass trapped flow analysis system* (ByT-FAS).[53] The ByT-FAS is applied to evaluate enzyme kinetic parameters by use of coupled enzyme assay (HK and G6PDH) and fluorescence detection.

Flow injection analytical biosystems based on *open-tube and packed bed enzyme reactors* have been compared.[52] Three different enzymes: urease (E.C. 3.5.1.5, 9002-23-5); creatine iminohydrolase (E.C. 3.5.4.21, 37289-15-9); and creatine amidohydrolase (E.C. 3.5.3.3, 37340-58-2) were covalently immobilized on CPG beads as the filling for the packed-bed reactor and immobilized covalently on the inner wall of nylon tube reactors. The authors notice, that packed bed reactors would be ideal for applications requiring a high sensitivity or measurements of low concentration, whereas open-tubular reactors will be best for applications involving samples with a high concentration or requiring saving in the reagents used or shorter analysis times.

7 IMMOBILIZED ENZYMES IN BIOSENSOR DEVELOPMENT

One of the first applications of immobilized enzymes in analytical chemistry was the construction of an enzyme electrode for glucose determination. An oxygen electrode, Clark type, was combined with a thin layer of GOD entrapped in a polyacrylamide gel.[53] Such enzyme electrode form a major category of so called *biosensors*.

Literature lacks a standardized definition of the term biosensor. Generally, the biosensor is a measuring device that contains a biological element.[54] The biological or biorecognition element may be an enzyme, antibody or microorganism system. Besides the biological element, or in sensor development called receptor, the biosensor consists of a transducer, that interprets the interaction of the analyte with the receptor as an electrical signal, related to the concentration (or activity) of a chemical or biochemical analyte (see Figure 10). For instance an enzymatic catalyzed reaction may produce ions, electrons, heat, color or changes in mass, used in the transducer to provide an electrical output. The receptor as a biorecognition element imparts the required high analyte selectivity to the transducer.

Usually, the enzyme is immobilized directly at the surface of the transducer or entrapped in gel or rather in membranes, fixed immediately at the transducer. Pertinent information about the immobilization of biological components for biosensor application is published by Eggins.[55] The optimization of the enzyme immobilization is one of the critical issues of biosensor development. Problems with long term stability of enzyme layers and long response times of biosensors have to be solved. Frequently, membranes used to separate the enzyme layer and the medium. Because of this, additional barriers, not only the enzyme kinetics but also diffusion effects, have to be taken into account. Furthermore, the biosensor signal is also influenced by temperature, inhibitors and pH value. In many practical applications, the highest efficiency can be achieved in combination with FIA systems.

Figure 10 General principle for a biosensor.

Advantages of biosensors are the detection of biological and chemical substances without the need for complex sample processing, simple method for use outside of a laboratory and the great potential of miniaturization by combination with the microsystem technique. Biosensors excel by a high selectivity and sensitivity.

In the following some examples of biosensors from the four principal transducer classes

- amperometric
- potentiometric
- optic
- calorimetric

are represented.

An extensive representation of the different transducer principles is given in Göpel, Hesse and Zemel.[56]

Amperometric biosensors monitor currents in the transducer generated when electrons are exchanged between a biological system and an electrode. Many blood glucose sensors are based on this principle. A prominent representative is the glucose analyzer Yellow Springs Instrument for the measurement of glucose (according to Equations 27 and 28, section 5.1) in whole blood. The applicability of this instrument has been expanded for the determination of for instance lactate, alcohol, uric acid and ascorbic acid. A list of enzyme electrode-based autoanalyzers and their application are given in Kress-Rogers.[51]

Potentiometric devices measure the accumulation of charge density at the surface of an electrode, especially pH-sensitive electrodes are used. Any enzyme reaction, affecting the acid–base equilibrium can be applied. Potentiometric enzyme sensors based on ion-sensitive field effect transistors (ISFETs) are also called enzyme field effect transistors (ENFETs). ENFETs are chiefly used for the determination of glucose, urea and penicillin. Moreover potentiometric enzyme sensors are employed for the determination of inhibitors. Copper(II) in water is determined in the ppm range without preconcentration, based on the urease inhibition and by means of an ISFET.[58] The urease is immobilized onto the pH-sensitive gate area of an ISFET. Authors used a photopolymer system

Figure 11 Schematic representation of the operating principle.

with urease to prepare photolithographically patterned enzyme membranes.

An example for the *optical* transducer principle are fiber-optic biosensors. A dual-enzyme fiber-optic biosensor for pyruvate determination is described.[59] This biosensor is based on the fluorometric detection of NADH and immobilized enzyme recycling system (see section 5.1) to amplify the sensitivity. The enzyme layer composed of lactate oxidase (LOD) and LDH is prepared at the tip of a sensing optrode. The described operating principle is illustrated in Figure 11.

The temperature changes during enzymatic reactions, as a consequence of heat exchange, are detected in biosensors with *thermal* transducer principle. A comprehensive representation of such transducer principle is given in Scheper.[60]

An integrated *thermal biosensor* array for multianalyte determination is described.[61] A single microchannel is partitioned into three distinct detection regions. Each of the regions is filled with one immobilized enzyme and contains a pair of thermistors for differential measurement of temperature changes, released by the enzymatic reaction. The pair of thin-film thermistors are placed upstream and downstream of each enzyme matrix. An enzyme-free region is arranged between two adjacent enzyme regions to damp thermal carryover. The authors demonstrate this sensor array with determinations of glucose, urea and penicillin. They applied GOD, urease and ß-lactamase (E.C. 3.5.2.6, 9001-74-5), immobilized on *N*-hydroxysuccinimide (NHS)-activated agarose beads.

Xie et al.[62] applied a *combination of two transducer principles*: a hybrid biosensor for simultaneous *electrochemical* and *thermometric* detection for determination of catechol. This biosensor is based on the tyrosinase (1.14.18.1, 9002-10-2) catalyzed reaction Equation (47):

$$\text{catechol} + \frac{1}{2}O_2 \xrightarrow[\text{response}:\Delta q]{\text{tyrosinase}} \text{1,2 benzochinon} + H_2O \quad (47)$$

with the electrochemical regeneration of catechol by Equation (48):

$$\text{1,2 benzochinon} + 2H^+ + 2e^- \xrightarrow[\text{response}:\Delta I]{} \text{catechol} \quad (48)$$

The hybrid biosensor concept uses the individual advantage of thermal and electrochemical detection principle.

ABBREVIATIONS AND ACRONYMS

ABTS	2,2′-Azino-di(3-ethylbenzthiazoli-sulfonic Acid-6)
ACHE	Acetylcholinesterase
ADP	Adenosine Diphosphate
Al-DH	Aldehyde Dehydrogenase
AOD	Alcohol Oxidase
AP	Alkaline Phosphatase
ATP	Adenosine Triphosphate
ByT-FAS	Bypass Trapped Flow Analysis System
CAH	Creatinine Amidohydrolase
CFI	Capillary Flow Injection
CK	Creatinine Kinase
CPG	Controlled Pore Glass
ENFETs	Enzyme Field Effect Transistors
ET	Enzyme Thermistor
FIA	Flow Injection Analysis
GOD	Glucose Oxidase
G6PDH	Glucose 6-phosphate Dehydrogenase
HK	Hexokinase
ISFET	Ion-sensitive Field Effect Transistor
LDH	Lactate Dehydrogenase
LMO	Lactate Monooxygenase
LOD	Lactate Oxidase
NAD	Nicotinamide Adenine Dinucleotide
NADH	Reduced Form of Nicotinamide Adenine Dinucleotide
NHS	*N*-hydroxysuccinimide
PK	Pyruvate Kinase
SIA	Sequential Injection Analysis
SOD	Sarcosine Oxidase

In kinetic methods or reaction-rate methods of analysis, the rate of a given reaction is measured and related to the concentration of the sought-for species. The instrumentation in kinetics is primarily designed to monitor the evolution of the analytical signal with time. Unlike in the traditional equilibrium-based approaches, where the signal is measured after the reaction has reached completion, in kinetic methods the signal is usually measured in the first few percent of the total reaction time. Therefore, the advantages and limitations of kinetic methods should be considered in their relations with equilibrium methods. Kinetic methods are faster than equilibrium-based methods since the user does not have to wait for a reaction to go to completion. They are relative methods that depend on changes in concentration and not on its absolute value and they could be more selective than equilibrium methods since the difference between reaction constants could be used to discriminate against an interfering species. The limitations of kinetic methods are a lower precision and a strong dependence on experimental conditions. The main factors that cause these limitations are the measured signal, which is small in comparison with that from an equilibrium reaction, and the dependence of rate constants on temperature, pH, ionic strength, etc. Therefore, the measurement systems used in kinetic methods should be sensitive and the experimental conditions should be kept strictly constant. The best results in kinetic methods are obtained with instrumental systems having a high degree of automation.

The main operations that should be carried out by the instrumentation in kinetic determinations are the mixing of the reactants, measurement of the detector signal in time and processing of data to obtain the reaction rate and concentration. The mixing of the reactants should be done in a time shorter than the reaction half-life and it is critical for fast reactions where required mixing times are of the order of milliseconds. In these cases the mixing is accomplished by mechanical systems that rapidly drive the reactants through a mixing chamber into an observation chamber. For slower reaction the best mixing procedures are based on automated flow analyzers that have different manifolds configurations adapted both to sample processing and to reactant mixing. After mixing, the reaction could be monitored in time either by stopping the flow and recording the signal or by passing the reacting plug several times through the detector and reading the signal after each pass. The measurement of the detector signal, after the reagents are mixed, could be done with a large variety of detectors, but the most commonly used detection systems are photometric and electrochemical. Photometric detection provides a short response time, specificity and the possibility of collecting full spectra very rapidly if photodetector arrays are used. Electrochemical detectors are simple and relatively inexpensive. The concentration of the analyte is determined from the slope of the detector signal. In many routine procedures the slope is determined by measuring the signal at one or two fixed points in time or by determining the time required by the signal to reach a predetermined level. These procedures have the advantage that they are rapid and need no supplementary instrumentation for data processing. Another approach in kinetic data processing, based on computer software, computes a curve that fits the experimental data. The slope or concentration is then extracted from the mathematical expression of the fitting curve.

1 INTRODUCTION

Kinetic methods of analysis are based on the determination of the rate of a given reaction in which the sought-for species is involved. The reaction rate is then correlated with the concentration. Consequently, the instrumentation in kinetics is primarily designed to monitor the evolution of the analytical signal with the time.

The use of kinetic methods is always considered in their relation with the well-established equilibrium methods because many analytical determinations could be

Encyclopedia of Analytical Chemistry

performed by either of the two types of method.[1–3] The main advantages of kinetic methods concern speed, relativity and selectivity. Kinetic methods have a potential speed advantage over equilibrium-based methods since the user does not have to wait for a reaction to go to completion. They are inherently relative methods and do not depend on absolute concentration but on changes in concentration. Kinetic methods could be more selective than equilibrium methods. The difference between reaction constants could be used to discriminate against an interfering species or to perform multicomponent determinations. Kinetic methods permit the determination of catalyst concentration, which cannot be readily determined by equilibrium-based methods.

The limits of kinetic methods should be carefully considered when using or designing instrumentation for kinetic determinations. The change in analytical signal that is measured is small in comparison with that from an equilibrium reaction. The consequence is a lower precision and the need to have very sensitive measurement systems. The rate of a reaction is dependent, via the rate constants, on experimental conditions: temperature, pH, ionic strength, etc. Therefore, the experimental conditions should be kept strictly constant. This is why automated systems give the best results in kinetic determinations and many of the modern instruments involved in rate methods have a high degree of automation.

The main operations in a kinetic method of analysis are the mixing of the reactants, measurement of the detector signal in time and processing of data to obtain the reaction rate and concentration. For each of these stages a unit in a block diagram of the instrument could be identified. A general block diagram of a complete instrumentation system for reaction rate methods is given in Figure 1.

The mixing of the reactants is a key operation in kinetic methods. In most kinetic methods the use of the initial rate of reaction is recommended, which means that the rate measurement should be made just after the reaction was initiated. Therefore, the time taken for mixing should be shorter than the reaction half-life. In the case of fast reactions, the required mixing times are of the order of milliseconds. For these reactions the mixing is accomplished by mechanical systems that drive the reactants through a mixing chamber, rapidly enough to have turbulent flow and rapid and thorough mixing. The observation is made in a region very close to the point where the reactants were completely mixed.

For slower reactions, the mixing could be done manually or with automated systems. Flow analyzers are the most widespread instrumental solution for the automation of kinetic methods. Once the reactants have been mixed in the analyzer manifold, the reaction could be monitored in time either by stopping the flow and recording the signal or by passing the reacting plug several times through the detector and reading the signal after each pass.

Figure 1 Block diagram of a complete instrumentation system for reaction rate methods. [Reprinted with permission from H.V. Malmstadt, E.A. Cordos, C.J. Delaney, *Anal. Chem.*, **44**(12), 26A–41A. Copyright 1972 American Chemical Society.]

The monitoring of the analytical signal after the reagents are mixed could be done with a large variety of detectors that should be selected considering the type of reaction and its rate. The detectors should be sensitive enough to detect small changes in the monitored parameter and their response time must be much shorter than the reaction half-life. The most commonly used detection systems are electrochemical and photometric. Electrochemical detectors are simple and relatively inexpensive. However, most detection methods used in kinetic determinations are photometric. Photometric detection is attractive because of the very short response time of modern photodetectors and the specificity of the spectrophotometric measurements. A wealth of information could be obtained if photodetector arrays are used to collect full spectra during the initial stage of the reaction.

In the final step of analysis the concentration should be determined from the slope of the detector signal. The slope could be determined explicitly if the signal was recorded in time, as a tangent to the kinetic curve. For routine applications, however, it is more convenient to simplify the slope determination by measuring the signal at one or two fixed points in time or to determine the

time required for the signal to reach a predetermined level (fixed-time and variable-time methods). These procedures predominate in routine analysis and even in many publications since they are rapid and need little or no supplementary instrumentation for data processing.

A more modern approach to kinetic data processing is based on computer software. Instead of the direct determination of the slope and concentration, a curve that fits the experimental data is computed. All the required data are then extracted from the mathematical expression for the fitting curve. The advantages of a curve-fitting procedure are multiple, e.g. a reduced effect of the noise and the possibility of extracting more information about rate constants and about the values of the equilibrium response by using a predictive manner approach. In the same category of advantages are the applications of error compensation methods and multicomponent analysis.

2 SAMPLE AND REAGENT PREPARATION, REACTANT PROPORTIONING AND MIXING

The sample and reagent preparation and the proportioning and mixing of the reactants are the most important, and sometimes the weakest, links in the chain of the instrumentation system. The development and automation of kinetic instrumentation in the last three decades focused on these parts of the diagram in Figure 1.

The sample preparation system must provide treatment operations that include dissolution in the case of solid samples, pH adjustment, extraction and removal of interfering components. The reagent preparation, in addition to simply preparing the reagent, is often used to dispense and mix the reagent in form of a single composite reagent.

The first approach to sample and reagent handling and mixing was that of manually pipeting sample and reagents into a reaction vessel that served both as mixing chamber and observation cell (the pour-and-shake technique). For a slow reaction the reactants could be mixed externally and then transferred to the observation cell. Most spectrophotometers have a pumping system that could aspirate the sample and reagent mixture and transfer it in a cuvette.

Today most kinetic instrumentation is automated to various degrees and adapted to fast or slow reactions. The sample and reagent preparation is often accomplished within the instrumental system, on-line, especially in flow analyzers. There are two main categories of techniques and analyzers in approaching the reactants preparation and mixing: stopped-flow analyzers for fast reaction and flow analyzers for slower reactions. A different novel approach that could be applied for fast reactions is based on continuous reagent addition.

2.1 Stopped-flow Analyzers

The stopped-flow technique consists of rapidly mixing the reactants by forcing the solutions through a mixing chamber and into an observation cell. The flow of solution is abruptly stopped, creating a back-pressure which completes the mixing, and the rate measurement is rapidly made. The more sudden the stopping, the faster the reaction can be observed. The stopped-flow technique is suitable for fast reactions with half-lives of a few milliseconds to few seconds.

The term ''stopped-flow'' is also used in continuous-flow techniques. It indicates a similar principle of operation that consists in halting the flow, recording the detector signal and measuring the slope of the obtained kinetic curve. However, the operating conditions are different from that of the normal stopped-flow technique. The relatively low flow rate of the solutions and the fact that sample and reagents are not mixed under high pressure and turbulent flow conditions does not allow the measurement of fast reactions. Therefore, the term ''stopped-flow mode''[4] will be used for this type of operation in continuous-flow techniques.

The basic components of a stopped-flow system are the driving syringes, mixing chamber, observation cell and the stopping syringe. The detection system used in connection with the observation cell should measure a certain property of the mixed solutions. The detection systems are spectrophotometric, fluorescence or both.[5] A few other types of detection systems for analytical application have also been devised.[6,7] However, many detection systems that are not photometric were intended rather for kinetic studies of reactions.

An example of an automatic stopped-flow system is shown schematically in Figure 2.[1] The driving syringes could be actuated by a motor and cam device or by a pneumatic system. Upon activation of the system, the sample and the reagents are drawn into the syringes. Then, after the three-way stopcock has been set in a proper position by the stopcock motor, the actuating system pushes the pistons and the solutions are rapidly driven out of the syringes. The solutions are forced into the mixing chamber and on to the observation cell. The reactants mixture flows through the observation cell until the flow is abruptly stopped by the stopping syringe. From the instant the syringe hits the mechanical stop the reaction rate curve could be recorded or the data fed to a computer. A family of stopped-flow kinetic curves obtained for the determination of lysozyme with fluorimetric detection is given in Figure 3.[8]

Figure 2 Schematic diagram of an automatic stopped-flow system. [Reproduced with permission from V. Malmstadt, E.A. Cordos, C.J. Delaney, *Anal. Chem.*, **44**(12), 26A–41A. Copyright 1972 American Chemical Society.]

Figure 3 Stopped-flow kinetic curve family. Kinetic curves with fluorimetric detection obtained for cresyl violet–sodium dodecyl sulfate–lysozyme system at different lysozyme concentrations: (1) 10, (2) 20, (3) 30 and (4) 40 mg mL^{-1}. Note that the initial reaction rate could be obtained within only 2 s. [Reprinted from B. Gala, A. Gómez-Hens, D. Pérez-Bendito, *Talanta*, **43**(9), 1413–1419 (1996), Copyright 1996, with permission from Elsevier Science.]

The efficiency of the stopped-flow system is dependent upon the flow velocity, mixer design and the distance between the mixer and the observation cell. It implies that the flow of solution must be turbulent. At a Reynolds number of about 2000 for short tubes with streamline entry, turbulent conditions, and consequently good mixing, are achieved at flow rates usually higher than 1 m s^{-1}. However, a very high flow rate could lead to cavitation effects produced by the unequal hydrostatic pressure of the streaming fluid in different portions of the tube. This will affect the precision of the reaction rate determinations, especially for spectrophotometric detection. Therefore, a compromise is made so that the flow rate is high enough to produce a turbulent flow and low enough to prevent cavitation.[9]

In obtaining a fast flow rate, the quality of the driving and stopping syringes is a key factor. The syringes are usually made from frosted-glass barrels and ceramic-tipped plungers. The problems that may arise in syringe functioning are those resulting from the difference in thermal expansion of the barrel material and plunger and those related to sealing and lubrication. Both of these problems could lead to breakage or ''blow-by'' during rapid acceleration that is required to obtain fast flow rates and to reduce the instrument dead time. Part of these could be avoided by using smooth-bore glass barrels and Teflon™ plunger tips.[10]

Most stopped-flow instruments are provided with thermostating systems for the driving syringes and reagents reservoirs to insure the constant temperature required by reaction rate measurements. Uncontrolled temperature changes may have undesirable effects on the rate of studied reaction and on the precision of analytical measurements. Temperature changes may result from the thermal gradient between different parts of the system or by heating during the compression and mixing of the reagents.[11]

The mixing efficiency, in turn, is dependent of mixing design. High mixing efficiencies are obtained using tangentially offset jets that promote a rotary motion of the fluid.[12,13] An increased number of jets and a higher jet velocity also contribute to higher efficiency. For a given mixer it means more jets with a smaller jet bore diameter. To avoid excess pressure drop in the mixer, the total area of the jet bores should be equal to that of the section of the observation cell. More than one mixer could be used, in cascade, both to increase the efficiency and to mix more than two different solutions.

A measure of the mixing efficiency is the dead time. It is defined as the time interval from the initial contact of the two solutions in the mixing chamber to the observation measurement point in the cell. If d_m is the distance, in meters, from the mixing chamber outlet to an observation point where the solutions are thoroughly mixed and v is the flow velocity in meters per second, the dead time is

given by Equation (1):

$$t_m = \frac{d_m}{v} \tag{1}$$

It is desirable to provide a dead time as small as possible. This could be accomplished either by improving the mixing design and thus decreasing the distance d_m from the mixer outlet to the point where the solutions are mixed or by increasing the flow velocity, v. Typically the dead time is in the millisecond range.[14,15]

In most instruments the mixer and the observation cell are part of the same unit. A schematic diagram of the driving syringe block and a vertical section of mixing and observation cell with spectrophotometric detection are given in Figure 4(a) and (b).[9] The syringe block could be considered as an aliquoting system that delivers solutions to the mixer. The sample and the composite reagent are mixed in a two-stage mixing chamber, introduced into the observation cell and pushed further through the block outlet to the stopping syringe. To minimize the dead time, the mixing chamber is located as close as possible to the observation cell.

The mixers and the observation cell are built from stainless steel, quartz,[16,17] fused silica[18] or polymers (Kel-F®).[19] In some of the commercial stopped-flow units the mixing chamber and observation cell are designed as a single block that could be easily fitted and removed from the cuvette compartment

of the existing spectrophotometers.[18] The design of stopped-flow syringe block implies that the volumes of solution delivered or their ratio are fixed. Therefore, a composite reagent is often used. To facilitate the adaptation of the method to more complex chemical reactions, mixing devices that allow predilution of the reactants have been devised.[20,21]

2.1.1 *Pulse-accelerated Flow*

Pulse-accelerated flow (PAF) is a procedure that allows the measurement of single-step reactions with half-lives from 0.5 ms to 4 μs.[22] The instrumentation is basically that of a stopped flow with motor-driven syringes (Figure 5). Instead of completely stopping the flow, a deceleration is applied and the flow velocity is reduced from 21 to 2 m s^{-1}. Reactions are observed as mixing takes place. Chemical rate processes are resolved from physical mixing rate process by variation of flow velocities under turbulent flow conditions. An integrating system of observation or position-resolved observation could be used. For position-resolved observation see section 3.2.

2.2 Flow Analyzers

Flow analyzers are the most widespread type of automated instruments that could be adapted both to equilibrium methods and kinetic methods. Flow analyzers are based on the sample treatment as it is transported by a flowing stream through a manifold made of interconnected tubing. There are two main techniques in accomplishing this method. One is based on the segmentation of the reagents flow with air bubbles [air-segmented continuous-flow analysis (ASCFA)], the sample being introduced into the flow by aspiration by the same pumping unit as for the reagents.[23] In the second technique, the reagent flow is continuous, nonsegmented, and the sample is injected into a carrier flow at a certain point of the manifold [flow-injection analysis (FIA)].[24,25] Combinations between these two techniques are also known.[26]

The main components of a flow analyzer are a propelling and aspiration system for reagents and sample, tubing manifold and a detector unit. For the air-segmented technique a debubbling device is included prior to the detection or an electronic bubble gate is used, so that the detection is done only when the solution is in the detector unit.[27] For FIA a sample injection valve is added, usually on the carrier stream.

The most frequently used device for obtaining a constant reagent flow is the peristaltic pump, although a number of other devices have been used: gas-pressure propulsion, syringes, linear and sinusoidal pumps.[28,29] Usually a six-channel peristaltic pump is sufficient for a single-channel analyzer.

The manifold consists of a coiled tube that insures radial mixing of sample and reagent. If more reagents have to be used in succession more streams are confluenced by adding more coils. Coiled tubes provide better mixing than straight tubing.[30] Tubes are made of glass, fused silica, plastics with inner diameters from about 1 mm down to 100 µm for capillary flow injection.[31–35] In the manifold structure could be included miniaturized packed reactors to process the sample further. The packed reactors could contain reagents,[36] immobilized enzymes,[37,38] ion exchangers[39] or polymer-based C_{18} materials.[40] Finally, the stream of reaction products flows through a detection system adapted to the small volumes of solutions.

Using the above-mentioned basic modules of the instrumentation a number of techniques are applied for reaction rate measurements.

2.2.1 Flow Analyzers in Stopped-flow Mode

The instrumentation includes the basic flow analysis set-up and a stop-and-go sequence provided by the computer or the circuitry that controls the instrument. The stream is started and when the mixture of sample and reagent

Figure 6 Schematic manifold of a flow injection system used in stopped-flow mode for reaction rate measurement (a) and the rate curves for two analyte concentrations (b). [Reprinted from J. Ruzicka, *Anal. Chim. Acta*, **261**(1–2), 3–10 (1992), Copyright 1992, with permission from Elsevier Science.]

reaches the detector the flow is stopped and the signal changes in time is monitored.[41] It could be accomplished as either an FIA[42] or an ASCFA technique.[43] An example of a stopped-flow injection instrumental set-up and the resulting kinetic curve is given in Figure 6(a) and (b). Here, the reactor is the called the sum of tubing, coils and T-mixers of the manifold where the reaction and/or subsequent reactions take place. By turning the sample valve a given amount of sample is injected into the carrier stream. The first rising portion of the signal indicates the moment the reacting plug has reached the detector. As the stream flows, the signal begins to decrease as the front of the reacting plug passes by. Stopping the flow after a time t_d (delay time) will result in an increase in the signal as reaction proceeds in the observation cell. The slope of the signal during the stop interval (reaction rate) is proportional to the analyte concentration. An example of a kinetic curve family obtained by stopped-flow injection is given in Figure 7 for glucose standards in glucose determination by the Trinder enzymatic reaction.[44]

2.2.2 Sequential Injection Stopped Flow

The techniques of sequential injection (SI) is based on the dispersion and mutual penetration of the sample and

Figure 7 Kinetic curves family obtained by FIA in the stopped-flow mode. The curves represent the absorbance signals at 504 nm in monitoring glucose concentration by use of Trinder reaction. Carrier flow was stopped at 90 s after injection. [Reprinted from G.D. Christian, J. Ruzicka, *Anal. Chim. Acta*, **261**(1–2), 11–21 (1992), Copyright 1992, with permission from Elsevier Science.]

reagents zones as they are stacked in a holding coil, adjacent to each other. The sampling valve has multiple ports so that sample, reagents and the carrier could be alternatively aspirated and propelled through the reactor to the detector (SI).[45] A diagram of the instrumental set-up and its functioning in the stopped-flow mode is given in Figure 8(a–e).

A high-precision piston pump or a peristaltic pump could be used to control the forward and reverse movement of the liquid flow. The first step is the aspiration of precisely measured volumes of carrier, sample and reagent into the holding coil (Figure 8a). Then the pump movement is reversed and the stack is propelled through the selector valve and reactor (Figure 8b) to the detector. The reversal of the flow creates a composite zone in which sample and reagent zones mutually penetrate. When the stack reaches the detector, the pump stops the flow (Figure 8c) and from this moment the kinetic curve could be recorded or the reaction rate could be determined (Figure 8e).

SI requires a simpler mechanics than flow injection. It uses a single pump, a single valve and a single channel. By designing appropriate software the SI technique becomes very versatile in configuring the analytical systems. Injection volumes, reaction times and zone dispersion could be changed via the computer by varying stroke volumes, flow rates and stopped-flow time.

In a recent kinetic application, SI was used for mechanistic studies and kinetic determination of bromazepam.[46]

Acta*, **261**(1–2), 11–21 (1992), Copyright 1992, with permission from Elsevier Science.]

2.2.3 Flow Recycle Analyzers

The kinetic information is obtained by passing the reacting plug several times through the detector until it is completely dispersed into the carrier.[47,48] After each pass the signal shows a peak. The number of peaks obtained per sample is a function of its volume, flow rate and the reactor length. The envelope of the maximum (or minimum) of these peaks defines a kinetic curve that allows the application of conventional kinetic methods of determination and calculations of the partial reaction orders and rate constants. The technique could be implemented both with unsegmented flow or air-segmented flow systems. The air-segmented flow system gives lower dispersion and shorter peaks than nonsegmented flow procedure.[49]

The instrumentation involves, in addition to the basic modules of a regular flow analyzer, a switching valve and a unidirectional peristaltic pump. A diagram of a flow recycle system, unsegmented type, and a typical kinetic curve are given in Figure 9(a–c).[50] It works as an open–closed system. The sample is injected and carried until it passes through the detection system. Then the valve is switched and the reacting plug is transported in a closed loop by the unidirectional peristaltic pump. Instrumental versions of this technique in which the recycling is done using only the main peristaltic pump and a pair of switching valves are also known.[51]

(a) Sample injection and delay period until the reacting plug reaches the detector. (b) Closing of a loop by actuating the switching valve. (c) Typical plot of the detector signal. [Adapted by permission of The Royal Society of Chemistry from M. Silva, *Analyst*, **118**(6), 681–688 (1993).]

2.2.4 Flow Reversal Analyzers

The kinetic response of this type of analyzers is obtained by passing the reacting plug several times through the detector, but alternately in opposite directions.[52–54] The manifold for an air-segmented flow reversal analyzer and the corresponding response curve are given in Figure 10(a–c). The reversal of the flow direction, via the selecting valve, is activated when the detector signal falls

Figure 10 Diagram of an air-segmented flow reversal analyzer. SV, switching valve; D, detector; W, waste. (a) and (b) flow reversal by the switching valve; (c) typical plot of the detector signal. [Adapted by permission of The Royal Society of Chemistry from M. Silva, *Analyst*, **118**(6), 681–688 (1993).]

to zero. Compared with the normal flow, peaks obtained by flow reversal are narrower and more Gaussian, with lower dispersion. This is mainly because of the way the flow is circulated and the fact that the sample does not travel through the whole flow injection system. This type of analyzer is particularly well suited for very slow reactions. Flow reversal analyzers are used both in unsegmented flow and in air-segmented flow modes.[49]

2.3 Continuous Reagent Addition Method

In this method, the reagent with which the analyte reacts is added continuously, at a constant rate, to the solution of the analyte and other reaction ingredients.[55] The instrumentation is fairly simple and consists of a reaction vessel with an adequate stirring and an automatic burette. Using an immersion probe for photometric detection allows for smaller reaction vessels and lower sample consumption (Figure 11a).[50] The analyzers of this type are especially suited to fast reactions and offer a major alternative to the stopped-flow analyzers. The analyte concentration during this addition varies because of both reaction and dilution. The overall reaction is of second order.

A typical kinetic curve is given in Figure 11(b). There are two portions on this curve, which are of analytical interest. The first is the initial concave segment that conforms to Equation (2):

$$\Delta S = 0.5\varepsilon_p u V_0^{-1} k[\mathrm{R}]_0[\mathrm{A}]_0 t^2 \qquad (2)$$

where ΔS is the change in analytical signal, ε_p the molar absorbtivity of the product, V_0 the initial sample volume, k the second-order rate constant, $[\mathrm{R}]_0$ the reagent concentration in the automatic burette, $[\mathrm{A}]_0$ the initial concentration of the analyte and t time. Equation (2) shows that the analytical signal is directly proportional to t^2. The analyte concentration could be determined from this segment of the kinetic curve using the initial reaction method.

The second segment of interest on the kinetic curve is the linear intermediate portion that follows Equation (3):

$$\left(\frac{\mathrm{d}S}{\mathrm{d}t}\right)_m \approx 0.55\varepsilon_p[\mathrm{A}]_0 \left(\frac{k[\mathrm{R}]_0}{V_0}\right)^{1/2} \qquad (3)$$

where the subscript m signifies the maximum reaction.

In comparing the two possible approaches to the kinetic curve, the maximum reaction method yields a smaller error, for instrumental reasons, while the initial reaction method is less affected by side reactions since the measurements are made at the beginning of the reaction. However, the maximum reaction method is preferred since it is less sensitive to between-run variations arising from the rate constants and the measurements are made on a much larger linear portion.[56]

The continuous reagent addition method was applied for single-element determinations[57–61] and on pharmaceuticals,[62–66] biological[67] and clinical[68] samples.

2.3.1 Continuous-flow Stirred Tank Reactor

The principle of the continuous flow of reagent could be used to apply the analyte pulse perturbation (APP) technique on oscillating chemical reactions and to use these reactions for analytical purposes. The most convenient instrumental set-up for APP is the continuous-flow stirred tank reactor (CSTR). The continuous-flow component of a CSTR is provided by a peristaltic pump, that pumps the required reagents into a thermostatted receiver. The reagent mixture is well stirred and its volume is kept constant by an overflow channel provided by the same peristaltic pump. The reaction is monitored in the receiver, usually by photometric or electrochemical detection. The CSTR could be considered a homogeneous system, where mass and energy are continuously exchanged with the surrounding environment and the reactions occur in far from thermodynamic equilibrium conditions.[69]

The APP technique is based on the change in amplitude or period of an oscillating reaction produced by a microvolume of an analyte solution added to the reactant mixture.[70] The reactions most frequently used are the Belousov–Zhabotinskii reaction, based on the oxidation of malonic acid by bromate ions in concentrated sulfuric acid, and copper oscillators based on the oxidation of KSCN by H_2O_2 in a strongly alkaline medium, which is catalyzed by traces of copper. The APP technique has been used on copper oscillators for the determination of vitamin B_6,[71] gallic acid and paracetamol,[72,73] resorcinol[74] and glutathione.[75]

3 REACTION MONITORING SYSTEMS

Any suitable means of monitoring the concentration of a chemical species can be used in reaction rate methods. Most frequently, spectrochemical and electrochemical methods are used for monitoring but a smaller number of methods based on other chemical or physical parameters have been described. In selecting an appropriate transducer, the nature of the monitored species, the type of reaction and its rate must be considered. The transducer should be sufficiently sensitive to provide detection of very small changes in measured reaction parameter and must have a response time which is short relative to the reaction half-time to prevent distortion of the resultant rate curve.

The kinetic information could be obtained using single- or multichannel detection systems. Single-channel detection systems produce a single response, proportional to the reactant or product concentration versus time. Multichannel or multidimensional detection systems provide simultaneous (or quasi-simultaneous) responses from the same chemical reaction. The multidimensional detection could be achieved by using a single type of detector or by combining more types of detectors.[2]

3.1 Single-channel Detection

3.1.1 Electrochemical Monitoring

Electrochemical-based devices are attractive mainly because of instrumental simplicity and relatively low cost. Most of the instruments are based on potentiometric and amperometric detection but detectors based on conductometry, chronoamperometry and voltammetry are also used. Since most kinetic determinations are accomplished by means of flow analyzers, the detectors for this type of instrumentation will be considered.

Potentiometric detection is based on monitoring the potential of an indicating electrode. The main indicating electrodes in kinetic determinations are metallic electrodes, carbon-based electrodes, ion-selective electrodes (ISEs) and enzyme electrodes. The reference electrode is usually an Ag/AgCl electrode.

Copper-wire electrodes were used for the detection of amines in a flow-injection system.[76] A flow cell containing eight Ag electrodes in the carrier channel and one Ag electrode in the reference channel was used for determination of Ag^+ and iodide ions.[77] The potential of a silver metal electrode was measured to detect the metal cyanide complex formation. Ag, Hg(II), Fe(III), Cu(II), Zn, Co(II) or Ni(II) were determined in a flow-injection analyzer with 0.29 mM cyanide solution as carrier.[78] Aluminum ions were detected by an Al-wire indicator electrode with an Ag-wire reference electrode in a carrier solution of 1 mM fluoride in 0.05 M acetate buffer of pH 5.[79]

ISEs and biosensors are known for many analytical species. The electrode response time varies according to both the type of electrode and the conditions under which is used. For detection in flow analyzers where the electrode volume should be small and its response time short, the ionophore is incorporated in a polymer and applied as a thin layer on a metallic wire (ion-selective coated-wire electrodes).[80–82]

A solid-state Br^- electrode in conjunction with a double-junction Ag/AgCl reference electrode was used for potentiometric monitoring of Br in the kinetic determination of pyridoxine.[83] A Br^--selective electrode is used for monitoring the potential oscillations in the Belousov–Zhabotinskii reaction in kinetic determination of hexacyanoferrates.[84] Fluorine-sensitive electrodes have been applied for a number of kinetic determinations. The determination of carbocysteine in colored pharmaceuticals based on monitoring of its reaction with 1-fluoro-2,4-dinitrobenzene, catalyzed by

hexamethyltrimethylammonium bromide micelles, was performed using a F^--selective electrode.[85] The same type of electrode was used for kinetic determination of ethylenediaminetetraacetic acid (EDTA) and citrate by the displacement of fluoride from aluminum(III) fluoride complexes.[86] A kinetic method based on a fluoride-selective electrode was applied in the determination of alkaline phosphatase in serum.[87] Kinetic determination of primary and secondary amines was accomplished based on their reaction with 1-fluoro-2,4-dinitrobenzene monitored by an F^--selective electrode.[88]

Copper was determined based on its catalytic effect on the reaction between hexachloroantimonate and hydroxylamine. The rate of the reaction was measured potentiometrically with an Sb(V) ISE using 1,2,4,6-tetraphenylpyridinium iodide as electroactive material in a poly(vinyl chloride) (PVC) membrane.[89] A Pb ISE was used for determination of citrate by monitoring the citrate in drinks and pharmaceutical products. The method is based on inhibition, by citrate, of crystalline growth of lead carbonate seed crystals.[90]

Amperometric detection involves monitoring the current between a working electrode and an auxiliary electrode at a given potential difference between the working and a reference electrode. The working electrode could be metal (Pt, Co, W), modified metal (metal hexacyanoferrate, Pt enzyme) or carbon-based (vitreous carbon, graphite, carbon paste, modified carbon paste). The auxiliary electrode is Pt, a carbon-based electrode or sometimes metallic parts of a cell. The reference electrode is Ag/AgCl or a saturated calomel electrode (SCE). The potential of the working electrode is a function of the species to be measured and of the type of electrode. Detection limits are in the range of 1 μM. Lower detection limits could be achieved with chemically modified electrodes. Detection cells could have a volume in the range of microliters.

Amperometric detection has been extensively used in conjunction with rotating bioreactors. The cell comprises a stationary Pt-ring electrode, a stainless-steel auxiliary electrode and an Ag/AgCl reference electrode.[91] It was used for determination of glucose, via the H_2O_2 produced enzymically, kinetic determination of fructose and ascorbate in food,[92] determination of choline esters in pharmaceuticals[93] and in comparative studies of bioreactor systems.[94] An amperometric oxygen sensor with a Pb anode, an Ag cathode and a polyethylene membrane was used for the determination of Co by measuring the rate of its reaction with dissolved oxygen.[95] For kinetic determination of As(III) the limiting diffusion current is measured, in a solution of KBr and KIO_4, with a polarograph with a Pt indicator electrode at 0.4 V and an SCE. The oxidation of KBr by KIO_4 is subject to an induction period, the length of which is directly proportional to the As(III) concentration.[96] Hg could be determined based on its catalytic effect on the photooxidation of EDTA by iodine. The reaction rate is measured amperometrically from the time required for the iodine reduction current to decay to zero at −100 mV vs SCE.[97] The determination of nitrate is based on the same photochemical reaction as above, but with an inhibitory effect. A platinum indicator electrode and an SCE is dipped into the EDTA and iodine solution and the current–time curve is recorded at a constant potential of 100 mV.[98]

Biamperometric detection is based on the measurement of current between two identical electrodes. The detector is simpler than in amperometric detection and consists of two opposing platinum electrodes in contact with the carrier stream. A potential difference of 10–500 mV is applied between the electrodes and the resulting current is measured. The current can flow only when both reduced and oxidized forms of a couple are present in the cell. The detection limits are in the range of 1 μM. Biamperometric detection was used in the kinetic determination of vitamin B_1 during their reaction with coulometrically generated iodine.[99]

For *conductometric detection*, a computer-controlled bipolar pulse conductivity system has been developed for use as a detector in reaction rate determinations. The system could perform discrete conductance measurements in 30 μs and could be used as detector in stopped-flow studies.[6] Kinetic monitoring based on conductometry was applied to the synthesis of *N*-α-benzyloxycarbonylalanylphenylalaninamide in the presence of *Pseudomonas aeruginosa* elastase. After the reaction was initiated the change in conductance was recorded allowing a precise measurement of the initial reaction rate.[100] A conductometer with facilities conductivity compensation was used to monitor the bromate–iodide–ascorbic acid Landolt reaction. The time interval between the initial rise in conductivity on mixing the solutions and the attainment of a minimum conductivity value was taken as the reaction time.[101]

The effect of lanthanide ions on the kinetics of glutamate dehydrogenase with NADH as coenzyme was monitored with a *chronoamperometric method*. The initial reaction rate, and hence the activity of glutamate dehydrogenase, was determined by measuring the decrease in the steady-state limiting current of NADH oxidation at a vitreous C electrode at ±0.8 V vs SCE.[102] *Chronopotentiometry* with a Br^--selective chalcogenide glass electrode was applied in the kinetic determination of vanadium in natural waters and wastewater.[103]

Polarographic-based detection was used for catalyzed reactions with the reaction step and detection step performed separately. The catalyzed reaction is quenched after a fixed time. The concentration of one of the

species involved in the reaction is determined by a form of polarography. This procedure was applied to the determination of ascorbic acid and Fe(III) using single-sweep oscillopolarography[104,105] and nitrate by differential-pulse polarography[106] with a dropping-mercury electrode as the working electrode and a Pt counter electrode.

3.1.2 Photometric Monitoring

Photometric monitoring makes up the bulk of detection systems used in reaction rate determination, as demonstrated in the comprehensive reviews by Mottola et al., dedicated to kinetic determinations, published biannually in *Analytical Chemistry*.[107–109]

Photometric systems for measuring ultraviolet and visible absorbed, fluorescent or chemiluminescence radiation are equipped almost exclusively with photomultiplier tubes or photodiodes (PDs). Both of these transducers have a response time in the nanosecond range, allowing very fast reactions to be followed. The type and model of transducer selected for a given type of chemical system and spectroscopic method should provide the highest signal-to-noise ratio. Photomultiplier tubes exhibit better characteristics than PDs when low light levels are measured (photocathodic current below 10^{-9} A) and are recommended for measurements requiring a narrow absorption bandwidth and for fluorescence, phosphorescence and chemiluminescence spectroscopy.[110] PDs are advantageous for the measurement of higher light intensities as in molecular absorption spectroscopy where the large bandwidth allows the use of filters or monochromators with larger bandwidth.[111]

Most detection systems are commercially available spectrophotometers, which could be used, for slow reaction, with no major modification. For spectrophotometers used as a detection system in flow analysis, a flow-through cell should be adapted to the cell compartment of the spectrophotometer.

A series of flow-through cells were used in connection with colorimeter heads using light-emitting diodes (LEDs) as light sources and PDs as detectors. Such a colorimeter head is very cheap, has a small volume and does not require very stabilized sources. The band gap in LEDs could be altered in the manufacture so that LEDs having source peak emission at different wavelengths in the visible region are currently available. The LED emission band-pass is less than 15 nm at half emission peak height, which is comparable to the band-pass of an interference filter. Such a colorimeter head was built in a double-beam version with an LED of appropriate wavelength and two PDs. One PD is mounted in the light path and the other perpendicular to the path. A beam splitter fabricated from a rod cut at one end at a 45° angle reflects about 50% of the light to the detecting PD while the remainder of the light strikes the reference PD.[112]

3.1.3 Fluorimetric and Chemiluminescence Monitoring

Fluorimetric and chemiluminescence monitoring implies the detection of relatively low light intensities. Most commercial spectrofluorimeters are provided with facilities to measure both fluorimetric and chemiluminiscence signals.

Fluorimetric detection is a multiparameter technique that involves an absorption wavelength and a luminescence wavelength. The bandwidth and the polarization of both light beams could be separately controlled. This, in combination with the control of other parameters, such as beam modulation, provides the fluorimetric methods with a high selectivity.[113]

Fluorimetric monitoring in reaction rate methods has been applied for both catalyzed and noncatalyzed reactions. Kinetic fluorimetric determination has been reported for a number of metallic ions, e.g. iron,[114] cerium,[115] aluminum,[116] tin,[117] nickel[118] and vanadium.[119] The combination of stopped-flow or flow injection in the stopped-flow mode and fluorimetric monitoring of reaction rate has been used for pharmaceuticals, drugs, pesticides and biological samples.[8,120–126] The potential of reaction rate methods in pesticide and drug determinations was demonstrated by using stopped-flow immunoassay. The negative effect of the sample matrix could be avoided by monitoring the initial rate of an antigen–antibody reaction. Using fluorescence polarization as the detection system significantly enhances the selectivity of the method.[127–129] In this case, a polarizer polarizes the excitation beam while a second polarizer is introduced in the luminescence beam. Light intensity measurements could be made parallel or perpendicular to the polarization of the exciting light.

Chemiluminescence detection in reaction rate measurements involves a highly efficient system of mixing and a fast light detector that are motivated by the transient nature of the light emitted by chemiluminescent systems. This is why this type of detection is used in conjunction with stopped-flow techniques or continuous reagent addition coupled with spectrofluorimeters. Chemiluminescence detection was used for the determination of nitrogen oxides in environmental samples, based on $NO-O_3$ chemiluminescence[130] and in studies of the effects of surfactants on the rate of peroxyoxalate chemiluminescence reaction between bis{*N*-[2-(*N*′-methyl-2′-pyridiniumyl)ethyl]-*N*-[(trifluoromethyl)sulfonyl]}oxamide, H_2O_2 and a fluorophore.[131] Also, in the determination of serum creatinine using creatininase, creatinase and sarcosine oxidase, the detection was based on the chemiluminometric rate assay of H_2O_2 produced.[132] The continuous addition reagent technique was tested

for the Cu(II)-catalyzed reaction between luminol and H_2O_2 using a fluorimeter in energy mode at 425 nm for chemiluminescent reaction-rate determinations.[61] A stopped-flow procedure combined with chemiluminescence detection was reported for multicomponent kinetic analysis of chemiluminescence enhancers (protocatechuic and caffeic acids).[133] The chemiluminiscence of the bis(2,4,6-trichlorophenyl) oxalate–H_2O_2 system was used for the kinetic determination of phenothiazine drugs. The method was applied to the determination of acepromazine in horse plasma.[60] Chemiluminescence detection was used for the determination of alkaloids (psychotropic indole derivatives) by the maximum reaction rate method. An application of psilocin determination in mushrooms has been reported.[134] A kinetic method for tertiary aliphatic amines with chemiluminescence detection is based on the reaction between tertiary aliphatic amines and sodium hypochlorite in alkaline medium and in the presence of fluorescein as sensitizer. The chemiluminescence intensity was monitored using a photomultiplier at a rate of one reading every 7.5 ms. Detection limits were 2.7–7.7 mol. The method was applied to determine trimethylamine in fish and to study the degradation of fish during storage.[67]

Photon counting, as a detection technique fitted for very low light intensities, has been used in fluorimetry for drug determinations. A stopped-flow reactor was used in conjunction with a photon-counting spectrofluorimeter, equipped with a xenon-arc source, for the determination of nordazepam in urine and imipramine in blood serum.[127]

3.1.4 Other Types of Detection

Thermometric detection could be used for catalytic reactions. After the start of reaction the initial temperature change is usually proportional to the catalyst concentration if the reaction is first order with respect to the catalyst. The temperature of the reacting mixture is monitored using a thermistor connected to a Wheatstone bridge and having a sensitivity of $0.01\,^{\circ}C\,mV^{-1}$. Thermometric detection requires simple instrumentation and avoids interference from colored compounds and precipitates. Reaction rate determination by thermometry has been applied to the determination of single elements[135–142] and mixtures of elements[143–145] based on their catalytic effect in redox reactions and for the determination of enzymes.[146]

Surface acoustic wave (SAW) sensors are mass detectors that can measure a variety of other physical properties at the sensor surface. Most SAW devices consist of a piezoelectric crystal with two sets of interdigital transducers laid down on the crystal surface. When a time-varying radiofrequency potential is applied to one set of interdigital transducers, an acoustic wave is launched in the surface of the piezoelectric crystal. This wave travels across the surface of the crystal and is received by the second set of transducers, which converts the mechanical energy of the wave back into an electrical signal. The acoustic wave generated is very sensitive to material present at the crystal surface. The acoustic device is converted into a chemical sensor by application of chemically selective layer on the resonant crystal. The resonant frequency of the SAW device would be altered if a chemical component interacts with the selective layer.[147]

The use of SAWs in analysis is increasing because of their selectivity and sensitivity. In recent years a series of applications of SAW as detectors have been published for kinetic determinations of alkaline phosphatase and acid phosphatase,[148,149] trypsin and antitrypsin in human serum,[150,151] pancreatic lipase,[152] urea in human blood,[153] arginase–urease,[154] organophosphorus nerve agents[155] and organophosphorus pesticides.[156]

3.2 Multichannel Detection

Multichannel detection is the basis for multidimensional instrumentation. It offers a great deal more information about time-dependent systems than could be obtained from monitoring one signal versus time. Multichannel detection is accomplished mainly as photometric detection based on photodetector arrays. Such an array consists of a number of small photosensitive detectors, called pixels, which are part of a single integrated circuit. The array could be linear or two-dimensional. Typically, a linear array could have from 64 to 4096 photosensitive elements on a photoactive surface 2.5–50 mm long and a few millimeters wide. Linear arrays with 8196 elements are also known. A two-dimensional array could have from 64×64 to 4096×4096 pixels. The pixel size ranges from 9 to 27 μm. The sensitive element could be a PD, charged-coupled device (CCD) or charge-injection device (CID). Most arrays have a spectral responsivity from 200 to 900 nm but devices that respond from 1 to 1000 nm are also available.[157]

By placing the photodetector array in the focal plane of a spectrometer, each element provides the information for a different wavelength and a full spectrum in absorption, fluorescence or chemiluminescence mode could be obtained in a matter of milliseconds or less. This allows for the monitoring of multiple species, observation of transient intermediates and correction for background absorbances. An example of a time–wavelength recording using diode arrays is given in Figure 12 for the iron-catalyzed reaction between leucomalachite green and peroxodisulfate.[158] The absorbance peak on the left indicates a catalytic effect produced by iron(II) and the higher peak in the middle a catalytic effect of both iron(II) and iron(III).

Figure 13 Position-resolved observation with photodetector array. A masked CCD array is placed parallel with the observation tube. The illumination permits observation perpendicular to the direction of solution flow. [Reprinted with permission from M.R. McDonald, T.X. Wang, M. Gazda. W.M. Scheper, S.W. Evetts, D.W. Margerum, *Anal. Chem.*, **69**(17), 3513–3520. Copyright 1997 American Chemical Society.]

Two types of spectra, absorption and fluorescence, could be also obtained simultaneously. A bifurcated fiber-optic light pipe and a spectrograph with an intensified array detector are used. The measurement circuit is operated in the time-sharing mode so that a single array collects both the absorbance and fluorescence signals.[159]

Spectrofluorimeters in a T format configuration could be used for the simultaneous determination of two species. In order to avoid spectral overlap the method requires that the reaction products of the analytes have similar excitation wavelengths and very different emission wavelengths.[160] The fluorescence intensity, provided by the same measurement cell, could be read on two channels perpendicularly on the excitation beam, at two different wavelengths. An appropriate set of filters and monochromators could be used to provide the excitation wavelength and the emission wavelengths. Since in most instruments there is only one emission monochromator, the wavelength of the second emission arm is set by a filter. This experimental set-up was used for simultaneous determination of nordazepam and imipramine in blood serum by fluoroimmunoassay,[127] for neomycin and promethazine in pharmaceutical preparations[160] and for ampicillin and tetracycline in milk, by stopped-flow fluorimetry.[161]

The photodetector arrays could be used for position-resolved observation. The detector is placed in a parallel position along the observation cell of a continuous-flow system. The data collected at different points along the cell by each element of the array correspond to different reaction times. This method of observation is exemplified in Figure 13 for a PAF spectrometer.[22]

The reagent and sample solutions are brought together in a 10-jet radial mixer and enter the observation cell with a flow velocity of $21\,m\,s^{-1}$. A decelerating push is given and the flow velocity decreases to $2\,m\,s^{-1}$. During the push, the reactions are observed perpendicular to the direction of the flow by a masked CCD array detector which provides, at the end of the push, a complete set of three-dimensional data, in 128 points, on position, velocity and transmittance.

3.3 Combined Detection

The rate measurements are more susceptible to variations in experimental conditions than equilibrium-based measurements. Combined detection could be used to minimize the effect of different parameters on the precision of rate measurements. Instead of maintaining the experimental conditions perfectly constant, the parameters that influence the precision could be measured and then a normalized rate calculated. An instrumental set-up for monitoring fluorescence signal, temperature and pH is given in Figure 14.[162] The fluorescence signal is simultaneously monitored with temperature and pH, the main experimental factors that could influence the precision of reaction rate measurements.

By means of dedicated software, the measured rate is normalized to a value that would be obtained at predetermined temperature and pH values. By applying the software correction the precision of rate measurement improves with a factor of four for temperature variations

Figure 14 Block diagram of instrumentation for monitoring and compensating for between-run temperature and pH variations in kinetic-based determinations. [Reprinted from G.L. Campi, J.D. Ingle, Jr, *Anal. Chim. Acta*, **224**, 275–287 (1989), Copyright 1989, with permission from Elsevier Science.]

higher than 1 °C and more than one order of magnitude for a pH variation greater than 0.28.

Specialized spectroelectrochemical detectors for flow injection were built so that absorption spectra could be recorded simultaneously with potentiometric measurements. In one of these systems,[163] the cells have a rectangular flow channel of 15 × 5 mm with a reticulated vitreous-carbon working electrode, an Ag/AgCl reference electrode and an open optical window. The dead volume of the cells is 80 µL. Absorption spectra were recorded with a 2-nm slit width and a 2-s response time.

4 DATA HANDLING

The final step of a kinetic method of analysis is the determination of the analyte concentration based on the reaction rate measurement. In turn, the reaction rate is obtained by processing the signal provided by the reaction monitoring system.

In the first stages of the data processing the slope of the signal (or the slope of the tangent to the signal) should be determined. In some analytical systems the rate curve is recorded and the slope is determined, by various means, from this recording. However, for many routine analyses, the recording of a rate curve could be a tedious or an unnecessary operation. Therefore, simpler ways to extract the kinetic information were devised, so that one or a few data from the detector are sufficient for a point on the calibration curve.

B. Intermediate-rate	
3. Integrated-signal methods	

Much effort has been devoted to developing more efficient procedures for reaction rate measurement, starting with analog systems and continuing with computer-based methods. In an exhaustive review, Pardue[164] classified, in a broadly applicable scheme, the options available in processing the reaction rate data. A simplified version of this classification is presented in Table 1. For single-component methods the classification scheme has two main categories: direct computation methods and curve-fitting methods.

The methods in the first category include those that could be implemented by manual data manipulation and automation with analog electronic devices. The data that represent the analytical signal are used to compute the concentration directly. The second category was developed after the advent and the wide availability of low-cost computers in analytical chemistry and involves curve-fitting procedures.

4.1 Direct Computation Methods

4.1.1 Integral Methods

The integral methods subcategory includes some basic methods that were applied from the early stages of kinetic determination development: fixed-time and variable-time methods.[9,165–167] A schematic representation of the principle of these two methods is given in Figure 15(a) and (b), respectively.

4.1.2 Fixed-time Method

In the fixed-time method, the change in the reaction-monitor signal is measured over a predetermined time interval, Δt. The method could be implemented in making the signal measurement at one point, two points or multiple points. The fixed-time method has two main attractive features. The first is that the measured signal varies in direct proportion to the analyte concentration. If the signal is a linear function of concentration, such as absorbance in spectrophotometric detection, the signal change over Δt varies linearly with concentration. This makes the data much easier to process and the concentration could be computed using just a multiplication factor. The second attractive feature is related to the fixed interval of time used for measurement. It is more convenient to automate the method if a fixed time sequence is used. In manual processing of a large number of samples, a fixed-time method facilitates the sample processing sequence, so that the signal could also be measured in a sequence.

However, in applying the fixed-time method, the relationship between signal and concentration should be known exactly. Anything that affects this relationship should be taken into consideration for the full range of analyte concentration implied in the determination. The method is less attractive in the case of detectors that do not respond linearly with concentration.

In the one-point approach of the fixed-time method, the time interval for measuring the signal is considered from the origin of the rate curve. It is the simplest form of data processing, since a single measurement is made, but it has the disadvantages of not compensating for a fixed background or for curve nonlinearity. In the two-point mode, two signal measurements are made with a Δt time interval.

Figure 15 (a) Fixed-time and (b) variable-time methods exemplified on a pseudo-first-order reaction.

The signal difference, ΔS, for the two measurement points is used to compute the concentration. In comparison with the one-point approach, the two-point mode could compensate for the fixed background. However, it cannot detect the curve nonlinearity. The multiple-point approach implies the measurement of the signal difference between multiple points in time. The main merit of this approach is that it can detect nonlinear responses.

4.1.3 Variable-time Method

The variable-time method involves the measurement of the time required by the reaction-monitor signal to change by a predetermined amount. The reciprocal of the measured time interval is proportional to the concentration of the sought-for species. Unlike the fixed-time methods, here is not necessary to know the mathematical relationship between concentration and detector signal and the nonlinearity of the detector response is of little importance. The detection system should be sensitive enough to detect the predetermined reference point(s).

Among the disadvantages of the method is the fact that the measured parameter, the time interval, varies inversely with the analyte concentration following a relationship that is relatively complex except for zero-order reactions. Since the time for a reaction to reach a predetermined signal level is not predictable, it is less convenient to use the variable-time method for manually processing a large number of samples or for automation. In some cases the concentration of the sought-for species could be too small and the detector signal could not reach the predetermined level. This sets a limit for the lower concentration that could be determined in a convenient time span. Also, the systems using the variable-time method are more susceptible to random spikes of the signal that may cause false triggering of the measurement system.

The one- and two-point approaches could be applied for the variable-time method. Their relative merits and shortcomings are the same as for the fixed-time method.

4.1.4 Rate Methods

This category includes the methods in which the rate is determined instantaneously direct from the detector signal.[168] They could be considered as *derivative methods* since the electronic device used for rate determination is a derivative circuit. The circuit is very simple and provides the instantaneous value of the tangent at one point of the rate curve. Paradoxically, this is a limiting factor because at the required sensitivity for rate measurement the rate curve is accompanied by noise. The instantaneous slope of the noise is usually much greater than that of the signal and the final result is an amplification of the noise signal.[9]

4.1.5 Integrated-signal Methods

Integrated-signal methods use the integral of a portion of the rate curve. In the only method from this group the detector signal is integrated on two equal segments of the rate curve.[169] The integrated curve portions could be adjacent or separated by a certain time interval. For zero-order processes the difference between the integrated signals is proportional to reaction rate. The principal advantage of this approach is very low noise susceptibility. This particular method could be considered a form of fixed-time two-point method in which the noise is averaged by integration.

Neither rate methods nor integrated-signal methods have been used extensively in routine applications. One of the reasons is that their implementation requires a specialized device, a ratemeter. Also, integral methods, fixed-time or variable-time, were more convenient for routine analysis since they could be applied by simply reading the level of the detector signal or measuring an interval of time. An integrated-signal method that offers greater noise immunity and reliable results was developed at about the same time when the use of computers was expanding in analytical instrumentation. The principle of the method could be implemented much more easily by software so there was no reason to develop specialized instrumentation.

4.2 Curve-fitting Methods

The methods in this category are based on in-line or off-line data processing by a computer. Unlike direct computation methods, where the reaction rate is obtained by using a closed-form algorithm applied to a few experimental points, here a mathematical model is computed that represents the ''best fit'' of data obtained from the detector. The values of the parameters required by the kinetic determination are obtained from the equation that resulted from the fit. The curve-fitting procedure could be applied for either linear or nonlinear responses.

Linear responses are the commonest applications since they correspond to zero-order and pseudo-zero-order processes that are most frequent in kinetic determinations. A least-squares algorithm or a Kalman filter could be used.[170,171] Several well-known software packages such as ORIGIN® (Microcal) and EXCEL® (Microsoft) include a linear regression fitting option. In addition to obtaining the slope of the rate curve, which is the primary objective of the method, some other statistical parameters could be computed: intercept linearity, correlation coefficients and errors.[172]

The curve-fitting for *nonlinear responses* could be used to compute directly the concentration from the slope. The slope could be determined either at the reaction

beginning, where it approaches zero-order behavior, or at another point on the rate curve. In the former case the data manipulation is reduced to that of a linear response. In the latter case the concentration could be computed from the slope if some of the experimental parameters are kept constant. For a first-order reaction this means that the slope is always measured at the same point in time and the rate constant does not change during the reaction.

The curve-fitting procedure could be used in a predictive manner. The kinetic curve based on data collected in one stage of the reaction could be extrapolated to another time range, without the need to run the reaction to completion. It is possible to predict the value of absorbance corresponding to the steady state in a spectrophotometrically monitored reaction or the steady-state velocity from data collected before the steady state was achieved.[173–175]

Data processing by computer offers the possibility to apply error-compensating methods to overcome the sensitivity of kinetic methods to conditions that influence the rate constant and to implement multicomponent kinetic methods.[176] Details of these features of data processing step of kinetic methods are given in the article **Data Treatment and Error Analysis in Kinetics**.

ABBREVIATIONS AND ACRONYMS

APP	Analyte Pulse Perturbation
ASCFA	Air-segmented Continuous-flow Analysis
CCD	Charged-coupled Device
CID	Charge-injection Device
CSTR	Continuous-flow Stirred Tank Reactor
EDTA	Ethylenediaminetetraacetic Acid
FIA	Flow-injection Analysis
ISE	Ion-selective Electrode
LED	Light-emitting Diode
PAF	Pulse-accelerated flow
PD	Photodiode
PVC	Poly(vinyl chloride)
SAW	Surface Acoustic Wave
SCE	Saturated Calomel Electrode
SI	Sequential Injection

Luminescence-based kinetic determinations are of great analytical interest and flexibility as they combine the high selectivity of kinetic methodology with the low detection limits afforded by the different luminescence techniques.

1 INTRODUCTION

Luminescence techniques can be included among monitoring techniques for kinetic determinations. However, the typically high selectivity and low detection limits of the ensuing methods make them especially attractive for kinetic analysis, where measured concentration changes are usually quite small. Like other kinetic methods, the growth of luminescence-based kinetic methods has relied heavily on the availability of suitable instrumentation. Thus, many reaction rate methods were initially less precise and more time-consuming and tedious than conventional equilibrium methods because the reaction rate had to be manually extracted from the recorder tracing, which decreased the precision of the results and increased the data treatment time. In addition, the instability of luminescence instruments precluded wider use of dynamic measurements based on using luminescence detection. These problems have been overcome with the inception of electronic devices and computers that permit the automated acquisition of data as the process develops, and afford enhanced data handling. The availability of stable luminescence instruments, automated precise sample and reagent delivery systems, and improved temperature-control equipment has minimized the shortcomings of luminescence-based kinetic determinations, which are now effective alternatives to equilibrium determinations as shown by the abundant literature on their applications.

The use of dynamic luminescence measurements affords very low detection limits (better than those obtained with equilibrium methods in some instances). Thus, when a luminescent system yields a static background signal, which is very usually the case in analyses of real samples, discriminating it from the equilibrium analytical signals obtained at very low analyte concentrations can be difficult because both are static signals. However, when the reaction rate is used as the analytical parameter, its dynamic character makes it less strongly dependent on the background signal provided this does not change with time. Also, analytical measurements made at the beginning of the reaction are known to avoid or minimize the potential inhibitory effect of other constituents of the sample matrix.

The first reported application of the combination of luminescence techniques and kinetic methodology was the fluorimetric monitoring of initial reaction rates for the determination of the rate constants involved in the association and dissociation of flavin mononucleotide (FMN) with its apoenzyme.[1] The study, which was carried out by using a filter fluorimeter, led to the development of the many luminescence-based kinetic methods available today. Early fluorimetric reaction rate methods were reviewed by Ingle and Ryan in 1981,[2] who noted the scant practical use of kinetic fluorimetric methods. However, continual improvements in available equipment have helped to consolidate fluorimetry and other luminescence techniques to be consolidated as alternatives to the analysis of real samples using kinetic methodology.

Broadly speaking, luminescence-based kinetic determinations can be classified into four groups, as follows.

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

1. Determinations based on the rate of change of chemical composition with time, which is monitored by measuring the variation of the luminescence signal with time. These determinations involve the use of conventional kinetic approaches such as the tangent, fixed time, and fixed signal (or variable time) methods.[3] Determinations based on measurements of the induction period, which arises in Landolt reactions[4] are also included in this group.
2. Determinations based on the use of flow systems with luminescence detection. Measurements are obtained when neither physical (homogenization) nor chemical equilibrium has been attained by the time that the sample zone reaches the continuous detector, so these determinations are doubly kinetic in nature.
3. Determinations based on measuring the lifetime of the excited state of a chemical species, which is obtained as the molecules return from the excited state to the ground state.
4. Determinations based on the use of chemiluminescence (CL) reactions in which the intensity of the emitted light is recorded as a function of the time and the peak intensity or the integrated area under all or part of the intensity–time curve is used as the analytical parameter.

The different luminescence techniques are included in the first and second group as they are used only as detection systems; by contrast, those in the third and fourth group unavoidably involve two luminescence processes: photoluminescence (fluorescence or phosphorescence) and CL. All these determinations involve making analytical measurements while the system is under nonequilibrium conditions, so kinetics play a significant role. Although each group is commented on to some extent here, this chapter deals mainly with traditional kinetic determinations,[5,6] i.e. those in the first group, which also includes CL and flow methods based on kinetic methodology. For a more systematic discussion, they have been classified according to the luminescence process involved. The special features of immunoassay and automation justify coverage in separate sections. The last section describes selected examples of simultaneous determinations.

2 THEORETICAL PRINCIPLES

All luminescence phenomena are processes of an intrinsically kinetic nature as they involve the emission of ultraviolet, visible or near-infrared radiation from a molecule or an atom resulting from the transition of an electronically excited state to a lower energy state (usually the ground state). Thus, in photoluminescence processes, which involve the use of electromagnetic radiation as the exciting source and the transition from a singlet (fluorescence) or a triplet (phosphorescence) electronically excited state, measurements are carried out under conditions of dynamic change controlled by the rates of deactivation processes that follow the excitation. Figure 1 shows the typical rate constants for the different excited state processes.

Figure 1 Rate constants involved in the different excited-state processes: (S_0) ground state; (S_1) lowest excited singlet state; (T_1) lowest triplet state; (k_I) internal conversion for lowest excited singlet state; (k_F) fluorescence; (k_M) intersystem crossing between lowest triplet state and ground state; (k_P) phosphorescence; (k_{IS}) intersystem crossing. Wavy lines indicate nonradiative transitions.

The excited states responsible for luminescence phenomena have finite lifetimes that can be measured by applying time-resolved methodologies and used as additional analytical parameters. In principle, time-resolved measurements contain more information than do steady-state measurements, since steady-state values represent the time averages of time-resolved determinations. The temporal information given by the fluorescence or phosphorescence lifetime can be employed, usually in combination with other parameters, to identify compounds. Also, if two or more luminescent compounds have similar absorption and emission spectra but different luminescence decay times, the compounds can be distinguished from one another by differential kinetic analysis.

In general, the excitation of a luminophore with an infinitely short pulse of light provides the best approach to explaining the luminescence decay. The variation of

the luminescence intensity as a function of time after the excitation pulse is applied is assumed to conform to an exponential decay curve, since the luminescence decay process usually obeys first-rate kinetics (Equation 1):

$$I_t = I_0\, e^{-kt} = I_0\, e^{-(t/\tau)} \tag{1}$$

where I_t is the luminescence intensity at time t, I_0 is the maximum luminescence intensity during excitation and t is the time after removal of the exciting radiation. Parameter k is the first-order rate constant for the decay process and equals the reciprocal of the mean lifetime of the excited state, τ. When $t = \tau$, the luminescence intensity is equal to 1/e of its initial value. Thus, the luminescence lifetime is the time required for the luminescence intensity to decrease to 1/e of its initial value.[7] Experimental lifetimes, whether for fluorescence or phosphorescence, indicate the overall rate at which the excited state is deactivated, through both radiative and nonradiative processes.[8,9]

The intrinsic luminescence lifetime, τ_0, can be experimentally obtained, provided luminescence is the only mechanism by which the excited molecule returns to the ground state. For a fluorescent process, the relationship between τ_F (observed fluorescence lifetime) and τ_{F0} (intrinsic luminescence lifetime) is given by Equation (2)

$$\tau_F = \phi_F \tau_{F0} \tag{2}$$

where ϕ_F is the fluorescence quantum yield, which can be defined in terms of rate constants of fluorescence (k_F), internal conversion for lowest excited singlet state (k_I) and intersystem crossing (k_{IS}) as in Equation (3):

$$\phi_F = \frac{k_F}{k_F + k_I + k_{IS}} \tag{3}$$

Also, τ_F can be defined as a function of such rate constants (Equation 4):

$$\tau_F = \frac{1}{k_F + k_I + k_{IS}} \tag{4}$$

If a biomolecular quenching process were competing for fluorescence, then the term $k_Q[Q]$ would be added to the denominator, where k_Q is the rate constant for biomolecular quenching and $[Q]$ the concentration of quencher.

Similar expressions can be obtained for phosphorescence decay, but the relationship between the quantum yield (ϕ_P) and intrinsic (τ_{P0}) and observed (τ_P) lifetimes is different in this instance, as the triplet formation quantum yield (ϕ_T) must be also included, as in Equation (5):

$$\tau_P = \frac{\phi_P \tau_{P0}}{\phi_T} \tag{5}$$

where $\phi_P = [k_P/(k_P + k_M)][k_{IS}/(k_{IS} + k_I + k_F)]$, in which k_M denotes the intersystem crossing between the lowest triplet state and the ground state rate constant, and $\phi_T = k_{IS}/(k_{IS} + k_I + k_F)$. Thus, τ_P is given by Equation (6):

$$\tau_P = \frac{1}{k_P + k_M} \tag{6}$$

Additionally, if a quenching process were present, the term $k_Q[Q]$ would be added to the denominator, as in fluorescence. The situation would also be more complex if other phenomena such as photochemical or energy transfer processes were present.

Phosphorescence triplet states of organic molecules usually have relatively long mean lifetimes (at the level of milliseconds or greater), so measuring τ_P is fairly simple and can be accomplished with conventional commercial phosphorescence spectrometers. However, τ_F is much shorter, at the level of 10^{-8}–10^{-11} s, and its measurement is electronically a much more difficult task. Two general approaches to determining the fluorescence lifetime have been developed that are named time-resolved and phase-resolved methods, and are based on the use of two different types of techniques, namely: pulse fluorimetry, which relates measurements performed in the time domain; and phase and modulation fluorimetry, which relate to the frequency domain.[10,11]

With CL, where the molecule in the electronically excited state is produced by a chemical, biochemical (bioluminescence) BL or electrochemical (electroluminescence) reaction, the process is probably the most markedly kinetic among luminescent phenomena, as the emission intensity, I_L, in photons emitted per seconds, is directly proportional to the rate of the reaction involved, dC/dt, in molecules reacting per second, according to Equation (7):

$$I_L = \phi_L \frac{dC}{dt} \tag{7}$$

where the proportionality constant ϕ_L is the CL quantum yield or efficiency, in photons emitted per molecule reacting. The CL efficiency is the product of the excitation quantum yield, ϕ_{EX}, in excited states produced per molecule reacting, and the emission quantum yield, ϕ_{EM}, in photons emitted per excited state. Efficiencies ranging from 10^{-15} to nearly 1 have been observed. Higher values are usually associated with BL reactions; by contrast, the conventional CL reactions usually employed for analytical purposes have typical efficiencies of 0.001–0.1.[12]

Although the lifetimes of the excited singlet states that are responsible for CL emission have typical durations in the nanoseconds region, the emission of light persists for as long as the CL reaction takes place. Thus, the photophysics of the electronically excited

products of the reaction and the kinetics of the reaction are involved in the CL emission. This justifies the prominent role assigned to CL methods among kinetic-based approaches. In fact, two of the more important factors to be considered in developing a CL method are the efficiency of the CL reaction, which ultimately affects sensitivity and detection limits, and the reaction kinetics, which dictates precision and throughput. In practice, both parameters are affected by experimental conditions including solvents, concentrations, pH, and reagent purity.

3 PHOTOLUMINESCENCE

In addition to the fact that all fluorescence and phosphorescence methods are intrinsically kinetic in nature, both luminescence processes have been applied to reaction rate methodology, but fluorescence-based kinetic determinations are much more numerous than those involving phosphorescence measurements. Overall, phosphorescence analysis has not been so widely used as fluorescence analysis, owing to the special requirements of the former, which originally called for cryogenic solvents and liquid nitrogen temperature, and later for the immobilization of phosphors adsorbed on solid matrices. However, the inception of micelle-stabilized room-temperature phosphorimetry (MSRTP),[13] which uses heavy atoms, has promoted the use of phosphorimetry as a determination tool.

3.1 Fluorescence

Fluorimetry has so far been the luminescence technique most frequently applied to reaction rate methodology. It is a competitive alternative to photometric and electrochemical measurements when fluorescent species are involved, as it generally affords better detection limits and selectivity, and wider dynamic ranges. Thus, detection limits can be two or three orders of magnitude lower than those obtained with photometric detection. Even if the chemical system involves no fluorescent species, fluorimetry can still be used as the detection system by coupling with a fluorogenic species in a secondary indicator reaction, as in a number of reported enzymatic determinations.[14] Thus, a generic enzymatic reaction can be represented by Equation (8):

$$S + E \longrightarrow P + E \tag{8}$$

where S is the substrate, E the enzyme and P the product, and any of them is fluorescent. An indicator reaction can be coupled, as in Equation (9):

$$P + R + E' \longrightarrow P' + R' + E' \tag{9}$$

where R′ is fluorescent and R is not, and E′ is the indicator enzyme. The variation of the fluorescence with time may be related to the concentration of S or E and, also, to the concentration of an activator or inhibitor of the enzymatic reaction. The scope of kinetic methodology is thus wider than that of the total change method, where the reaction is allowed to reach the equilibrium so only the substrate concentration can be determined.

Advances in instrumentation have also been applied to enzymatic kinetic analysis. Thus, an integrated microfabricated device that performs automated enzymatic analysis has been reported.[15] Electrokinetic flow was used to control the dilution and mixing of reagents, and the β-galactosidase-catalyzed hydrolysis of resorufin β-D-galactopyranoside, which is hydrolyzed to the fluorescent resorufin, was used as a model system for enzyme kinetic determination. The microchip design used is shown in Figure 2. An enzyme assay performed on the microchip within a 20-min period required only 200 pg of enzyme and 7.5 ng of substrate, thus reducing the amount of

Figure 2 Diagram of the enzyme analysis chip. The channels terminate at reservoirs containing the indicated solutions. (Reproduced by permission of the American Chemical Society, from Hadd et al.[15])

reagent needed by four orders of magnitude relative to a conventional assay.

Methods for the determination of inorganic species based on fluorimetric reaction-rate measurements are relatively abundant.[5,6,16,17] Many are based on the use of redox reactions, where the inorganic species acts as a catalyst. This methodology has allowed the very sensitive determination of metal species such as iron and cobalt, which cannot be determined by other fluorimetric approaches, owing to their paramagnetism. Other determinations are based on activation or inhibition processes, using enzymatic reactions in some cases. The main shortcoming of many of these methods, particularly earlier ones, is that they were not applied to real samples. Also, the number of kinetic fluorimetric determinations for inorganic species reported in the last years has declined markedly. Kinetic methodology has scarcely been used in connection with complex formation reactions owing to their high rates, which are usually measured by using fast-mixing systems.

Fluorimetric determinations of organic compounds based on kinetic methodology generally involve uncatalyzed reactions. These reactions are as varied as the nature of the organic compounds themselves,[5,6] although oxidation and condensation reactions are the most commonly used. There has been a trend to automating these methods in recent years in various analytical fields, including clinical, pharmaceutical, environmental and food analyses. Although most kinetic fluorimetric methods utilize a reaction monitoring system that produces a single signal that is proportional to the reactant or product concentration, modern multidimensional instrumentation allows much more complete information about the chemical system to be derived. Thus, array detectors provide fluorescence spectra in a time short enough to be useful for extracting kinetic information with a view to monitoring multiple species, observing transient intermediates, obtaining information about species with overlapping spectra and correcting for background fluorescence.[2] Multidimensional detection can also be accomplished by combining two or more types of detectors. Thus, reaction rates can be corrected for the influence of temperature and pH during fluorimetric kinetic measurements by simultaneously monitoring fluorescence, pH and temperature.[18] A block diagram of the equipment used for this purpose is shown in Figure 3.

Long-wavelength fluorogenic reagents are being increasingly used to improve the selectivity of fluorimetric methods by avoiding potential spectral interferences of the sample matrix with analytical measurements, which are often encountered with conventional fluorescence reagents. The combined use of kinetic methodology and these reagents has been shown to boost selectivity through temporal and spectral discrimination of the analytical signal. This approach has been applied to the kinetic determination of proteins such as gliadins[19] and caseins[20] in foods, by reaction with a surfactant and suppression of the quenching effect of the surfactant on the fluorescence of the fluorophore. The increase in fluorescence intensity with time is directly related to the protein concentration.

The inception of computers in analytical chemistry has allowed new developments in data processing for kinetic fluorimetric determinations; applications, however, remain scant. For instance, the Kalman filter,[21] an algorithm for the recursive estimation of the parameters and states of a system from a series of noisy measurements, has been used to determine the parameters for data files with different rate constants, and has been applied to the fluorescent reactions of amino acids with phthalaldehyde.[22]

(I/V) current to voltage converter; (PMT) photomultiplier tube; (PT) reference vacuum phototube; (ADC) analog to digital converter; (CRT) cathode-ray tube screen. (Reproduced by permission of Elsevier, from Campli and Ingle.[18])

Dynamic fluorimetric detection has scarcely been used in combination with separation techniques. Recently, a reaction kinetic model combined with a number of theoretical and experimental variables was developed to evaluate the dynamic ranges and detection limits obtained for biotin as a function of the streptavidin concentration.[23] For this purpose, laser-induced fluorescence detection was used in postcapillary affinity detection for capillary zone electrophoresis.

3.2 Phosphorescence

Kinetic methodology has been used in phosphorimetry mainly to determine the lifetime of the excited triplet state, which is the analytical parameter in time-resolved phosphorimetry as shown in the following section. However, this approach has scarcely been used in analytical applications involving measuring the rate of formation of a phosphorescent system in solution using MSRTP. Similar to other analytical techniques, this can be done by recording the kinetic curve that reflects the variation of the phosphorescence with time and using its slope as the analytical parameter. This is especially useful when the phosphorescent signal is unstable or takes a long time to stabilize, which is very usual in phosphorescent systems and hinders application of phosphorescence methods to routine analyses. This approach has been applied to the determination of carbaryl[24] in the presence of sodium dodecyl sulfate (SDS) and the thallous ion. The advantages of this determination are noted in section 6.2. The stopped-flow (SF) mixing technique was required to measure the fast initial rate of the system.

The term ''kinetic phosphorimetry'' was coined in connection with a method for the determination of uranium,[25] based on laser excitation followed by temporal resolution of the phosphorescence signal. As noted in section 2, in the absence of side processes, the equation that describes the first-order kinetic decay of the excited species can be written as Equation (10):

$$\ln I_t = \ln I_0 - (k_p + k_q)t \qquad (10)$$

where I_t and I_0 are the phosphorescence intensities at time t and 0, respectively, and are proportional to the concentration of the emitting species, k_p is the rate constant for phosphorescent decay, and k_q is the rate constant for all other relaxation processes. The number of detected photons at any time t is proportional to the number of excited species. Thus, a linear fit of the phosphorescence intensity data in the above equation gives an intercept at time $t = 0$, $\ln I_0$, proportional to the number of excited species, irrespective of quenching effects. The luminescence from the analyte is related to its concentration using the intercept I_0 from the above expression in the calibration equation obtained with known analyte standards. The decay lifetime, τ, which is the reciprocal of $(k_p + k_q)$, corresponds to the negative reciprocal of the slope in the above equation. As a result, the linear fit of this equation allows the calculation of the concentration of the analyte and its lifetime. The use of a dye laser source is very appropriate for this type of spectroscopic measurement because of its high intensity, monochromatic radiation and the possibility of varying the excitation wavelength. Figure 4 schematically depicts the equipment required.

Figure 4 Schematic diagram of the kinetic phosphorescence analyzer: (R) reference cell; (S) sample cell; (L) focusing lens; (F) interference filter; (A) apertures to the detectors; (M) mirrors. (Reproduced by permission of the American Chemical Society, from Brina and Miller.[25])

The determination of uranium by using this methodology is based on the fact that the luminescence decay of an excited uranyl complex follows first-order kinetics,[25] so the intensity of the uranyl luminescence emission declines exponentially after excitation with each laser pulse and the logarithm of the luminescence intensity is a linear function of time. The luminescence intensity at time zero after termination of the laser pulse, the initial luminescence intensity, is proportional to the uranium concentration. The method has been applied to the determination of uranium in water, urine, milk and soil samples. Analyses of more complex biological samples have been limited because the organic components cause quenching of the luminescence associated with the uranyl ion. Quenching can compete with phosphorescence by shortening the excited-state lifetime and reducing the luminescence intensity, thus affecting the specificity,

sensitivity and accuracy of the method. However, analysis of these samples has been accomplished[26] by previously heating at 600 °C.

3.3 Time-resolved and Phase-resolved Luminescence

As noted in section 2, luminescence lifetimes can be determined by using time-resolved and phase-resolved methods.There is extensive literature about both approaches.[10,11] Briefly, in the time-resolved method, the sample is excited with a short-duration pulse of light, and the time-dependent decay of the fluorescence intensity is used to calculate the lifetime. In the phase-resolved method, the sample is excited with sinusoidally modulated light and the phase shift and demodulation of the emission, relative to the incident light, are used to calculate the lifetime. Each method has some advantages and disadvantages. The choice depends on several variables, including the nature of the sample, deviation of decay from ideality, and lifetime range desired.[7] However, only the time-resolved method allows the kinetic curve to be obtained. The resolution of spectrally similar fluorofors or phosphors based on differences in lifetime is suitable when instrumental or spectroscopic methods for simultaneous determinations fail, when it may be difficult to separate the components in the sample or when chemical treatment of the sample may increase analysis time or introduce contamination. It is very unlikely that two components will have the same lifetime as well as the same excitation and emission spectra.

The qualifier ''time-resolved'' has been also applied to a series of determinations involving no luminescence lifetime measurements. These methods are based on the use of chemical systems with relatively long luminescence lifetimes. Equilibrium measurements are obtained in the phosphorescence mode, using preset delay and gating times. Lanthanide chelates, which are the subject of the next section, have been widely used for this purpose. A very interesting analytical application of these chelates is their use as labels in time-resolved fluorescence immunoassays.[27]

3.4 Lanthanide-sensitized Luminescence

The high coordination number of lanthanide ions allows the formation of luminescent ternary complexes, where one of the ligands absorbs the excitation light and efficiently transfers the energy to the chelated ion, whereas the second ligand has a merely synergistic effect, removing water molecules, which are deleterious to lanthanide emission, from the coordination sphere of the ion. The analytical applications of lanthanide-sensitized luminescence are of great interest[28] since lanthanide chelates exhibit a special behavior as a result of the intramolecular energy transfer from the excited triplet state of the ligand to the emitting level of the central ion, which partly or completely circumvents the selectivity restrictions of luminescence methods. Thus, the large Stokes shifts and narrow emission bands of these chelates afford the spectral discrimination of the analytical signal, while their relatively long lifetimes enable temporal discrimination from analytical measurements made in the phosphorescence mode to avoid scatter, Raman and any fluorescence background signals. In addition, this time-resolved mode increases the analytical signal, as this is integrated over a longer period than in the fluorescence mode, which results in improved detection limits.[29,30]

This luminescence process can be considered a special type of sensitized phosphorescence. One difference between the use of lanthanide ions as energy acceptors instead of compounds such as biacetyl or 1,4-dibromonaphthalene is that, with the latter, the energy transfer is intermolecular; this accounts for the low efficiency relative to the former, which involves intramolecular energy transfer. One other difference of practical interest is that no oxygen removal is required. The most efficient energy acceptors among lanthanide ions are terbium(III) and europium(III), which form stable complexes with many organic compounds.[28]

Although the formation of lanthanide chelates is generally very fast and the luminescence signal rapidly stabilizes, it has been shown that the use of initial rate measurements instead of equilibrium measurements can improve the selectivity of a determination.[31] Figure 5

Figure 5 Kinetic curves obtained for propyl gallate (1 μg ml^{-1}): alone (A), and in the presence of octyl gallate (20 μg ml^{-1}) (B), lauryl gallate (10 μg ml^{-1}) (C), and gallic acid (100 μg ml^{-1}) (D). (Reproduced by permission of the Royal Society of Chemistry, from Panadero et al.[31])

shows the kinetic curves obtained for the terbium(III)-propyl gallate system in the presence of other gallate derivatives. As can be seen, the equilibrium signal is modified by these compounds, while the initial slope of the kinetic curves are unaffected. The usually high formation rate of lanthanide chelates precludes the use of the batch technique and justifies the use of the SF mixing technique, which, in addition, minimizes reactant manipulation and ensures a high throughput, as shown in section 6.2.

4 CHEMILUMINESCENCE

The CL process is probably the most markedly kinetic of the luminescent phenomena as the factors that affect the emission intensity are a combination of luminescence and chemical reaction rate aspects (see section 2). Thus, taking into account that CL measurements are dynamic in nature, because they are based on the detection of a transient light emission, all CL methods might be classified as kinetic methods. A large number of methods based on CL reactions have been reported in the last few years.

The analytical parameters most frequently employed in CL methods are the peak intensity and the integrated area under all or part of the light emission–time curve. In both instances, one must rigorously control the interval between initiation of the reaction and acquisition of data. However, formation and decay rates of CL reactions have been found to provide better precision and selectivity that conventional parameters, which, as shown in section 6.2, have been obtained by using SF mixing technique.[32] This section describes some general aspects about the analytical interest of the different CL processes, namely conventional CL, electrochemiluminescence and BL.

4.1 Conventional Chemiluminescence

The reactions used in CL methods can be direct or indirect,[33] depending on the origin of the CL. They involve the processes represented by Equations (11–14):

$$A + B \longrightarrow C^* \quad (11)$$

$$C^* \longrightarrow C + \text{light} \quad (12)$$

and

$$C^* + D \longrightarrow C + D^* \quad (13)$$

$$D^* \longrightarrow D + \text{light} \quad (14)$$

In the former case, the reaction produces the primary excited-state molecule, which is responsible for the subsequent light emission; in the latter process, known as a ''sensitized reaction'', the excited product is not the light emitter, but rather transfers its energy to a fluorescent acceptor, which then emits light. The use of sensitized CL has distinct advantages in the design of analytical systems, as optimum structural features can be designed and incorporated into separate chemical reactant and fluorophore molecules. The fluorophore is selected to provide the optimum compromise between excitation and emission wavelengths, chemical stability and quantum yield. This is in contrast to direct CL, where reactivity and fluorescence properties reside in a single molecule. Extensive literature on the different types of CL systems is available.[33]

The duration of CL reactions varies from very short (<1 s) to very long (>1 day). In any case, because the signal is transient, measurements of CL intensity are time-dependent, which dictates the choice of method for mixing the reactants. Batch luminometers are based on static systems where the sample is placed in a cuvette that is accommodated in the instrument and the CL reagent is added either manually (with a syringe) or via an automatic injector. The CL intensity is usually monitored over a preset time interval. This approach can be used when the CL reaction has a long lifetime, but it is unsuitable for reproducible monitoring of a fast CL reaction (<15 s). In the latter case, the use of flow systems allows the reactants to be mixed rapidly and reproducibly in front of the detector, as shown in section 6. The combination of CL detection and liquid chromatography (LC) is particularly attractive, but the sensitivity of CL detection and the selectivity of LC must be balanced against the incompatibility of the best mobile phase for separation and the best conditions for the CL reaction.[34]

4.2 Electrogenerated Luminescence

Electrogenerated chemiluminescence (ECL), also known as ''electroluminescence'' or ''electrochemiluminescence'',[35] is a process by which electrochemically generated reactants undergo high-energy electron transfer reactions in solution, to yield excited-state molecules. Usually, cation and anion radicals are produced from electron donor and acceptor molecules at an electrode surface, which is achieved by applying double step potentials to the electrode to give positive and negative potentials respectively. The radical species produced then undergo an electron transfer reaction to give the excited state of either or both reactants. Thus, the CL reaction takes place in the vicinity of an electrode and involves electrochemically generated active species. This technique retains the advantageous sensitivity and selectivity of conventional CL and affords greater control over the initiation, rate and course of the reaction, as this is produced by electrical stimulation. It provides a direct monitor of reaction rate, as the photon flux is proportional

to the rate of the oxidation or reduction that produces the excited species.

Although the ECL process has been studied for many years, it has only recently emerged as a useful tool for the determination of a variety of analytes.[36] The earliest research in this direction was aimed at studying the nature of the emitting state, the mechanisms by which it is produced and the efficiency with which the excited state is generated. Available methods are usually implemented in static electrochemical systems that are modified to include the optical measurement system, allow the reactants to be generated in situ and facilitate dismantling for cleaning. However, ECL detection systems for the flow injection (FI) and liquid chromatographic techniques have also been reported, as has the immobilization of ECL reagents to develop sensors and probes.[36]

The full potential of analytical ECL has not yet been realized, and further work is needed to overcome the problems posed by electrode fouling, to increase the stability and robustness of immobilized ECL reagents, and to improve flow cell designs, which are complicated by the incorporation of electrodes and an optical measurement device.

4.3 Bioluminescence

Bioluminescence is a type of CL in which visible radiation is emitted from living organisms or systems derived therefrom. BL reactions involve luciferase-catalyzed oxidation of luciferins, where luciferase is the enzyme and luciferin the substrate. The systems most widely used for analytical purposes involve firefly and bacterial luciferase.[33] The high sensitivity associated with BL detection has been exploited in the design of analytical methods with excellent detection limits. The basic kinetics of BL analysis, use of coupled enzyme reactions with a final luminescence step, amplification of luminescent reactions by enzymatic cycling and the use of BL in the assay of enzyme activity have been discussed.[37,38]

One recent application of kinetic methodology to BL analysis is the automatic determination of urea by using ATP-hydrolyzing urease, firefly luciferase and luciferin.[39] Light intensity was measured at 40 and 80 s after addition of the urease reagent. Also, a kinetic assay of glycerol for lipolysis studies was developed[40] by using photinus-luciferin 4-monooxygenase, luciferin and glycerol kinase. BL intensity was measured every 0.2 min for 1.2 min.

5 IMMUNOASSAY

Different luminescence techniques have been applied to the determination of species by using immunochemical reactions that have given rise to a number of homogeneous and heterogeneous immunoassays. Homogeneous immunoassay is known to be simpler and faster than heterogeneous immunoassay as it involves none of the incubation, separation and wash steps of the latter, but detection limits are generally higher, mainly as a result of the sample matrix background.

Many homogeneous immunoassays involving fluorimetric detection use fluorescein (λ_{ex} 492 nm, λ_{em} 517 nm) as a label. This compound has a narrow Stokes' shift, which can pose light-scattering problems; also, its fluorescence emission can be compromised with the background fluorescence from the sample matrix. However, this problem can be overcome by using fluorophores such as oxazines, thiazines or cyanines, which give emission bands more red-shifted than that of fluorescein, and measuring the initial rate of the immunochemical reaction in order to accomplish spectral and temporal discrimination, respectively, of the analytical signal as an alternative to the physical separation required in heterogeneous immunoassay. These compounds also exhibit a short fluorescence lifetime, which decreases the likelihood of nonradiative quenching processes. Despite their potential, the utility of these compounds as hapten labels in immunoassay has scarcely been studied because the covalent labeling efficiency of oxazine and thiazine dyes with carboxylic acid-containing analytes is low. However, the efficiency can be improved by using a bifunctional reagent such as a carbodiimide derivative. The combined use of kinetic methodology and an oxazine label, namely Cresyl Violet, has enabled the determination of 2,4,5-trichlorophenoxyacetic acid, a herbicide used to control shrubs and trees, in liquid food samples.[41] The high initial rate of the immunochemical reaction was measured by using the SF mixing technique.

One other homogeneous technique is fluorescence polarization immunoassay (FPIA), which is a competitive binding assay where the tracer (the antigen conjugate) binding with the antibody is directly measured without the need for a separation procedure. It relies on the fact that, when a molecule is excited by polarized light, the emitted light will also be polarized, provided the molecule does not rotate during the time elapsed between excitation and emission. Small fluorescent molecules rotate rapidly, and normally exhibit no fluorescence polarization; on binding to macromolecules, however, the rotation motion is slowed down and the fluorescence remains polarized. Thus, the tracer, which competes with the analyte for the antibody, will only exhibit polarized fluorescence (which will be inversely proportional to the analyte concentration) when bound to the antibody.

Fluorescence polarization is usually expressed as the degree of polarization P (Equation 15):

$$P = \frac{(A/B) - 1}{(A/B) + 1} \quad (15)$$

where A and B are the fluorescence intensities measured with the emission polarizer parallel and perpendicular, respectively, to the excitation polarizer. A variety of electronic and optical assemblies have been used[42] to perform fluorescence polarization measurements. Conventional FPIA involves measuring P when the formation of the tracer–antibody complex has reached or is close to equilibrium. However, measuring the variation of P with time (dP/dt) allows one to obtain the reaction rate of the tracer–antibody complex, which is inversely proportional to the analyte concentration. Kinetic methodology avoids or minimizes the static signal from the sample matrix, which is usually the main cause of the relatively high detection limits afforded by conventional FPIA. This has been demonstrated in the determination of therapeutic[43] and abuse[44] drugs, and also of atrazine.[45] Table 1 compares the detection limits obtained for some of these compounds by using equilibrium and kinetic measurements in FPIA.

The only requirement for application of kinetic methodology in FPIA is the availability of instrumentation enabling simultaneous measurements of the variation of A and B with time to be processed by a microcomputer in order to construct a polarization–time kinetic curve. A T-format spectrofluorimeter with two emission channels symmetrically arranged on both sides of the sample compartment and with the emission polarizers placed perpendicular to each other is a suitable choice (Figure 6). Conventional kinetic measurements (batch technique) are unsuitable in FPIA because the initial rate of the competitive antigen–antibody reaction is usually very high, but it can be obtained by using the SF mixing technique.

Both homogeneous and heterogeneous immunoassays have been developed using CL detection. Similarly to other immunoassay techniques, the CL homogeneous format is technically more simple, but it is subject to problems

Table 1 Comparison of detection limits obtained by using conventional and kinetic measurements in FPIA

Compound	Detection limit ($\mu g\,L^{-1}$)	
	Conventional FPIA	Kinetic FPIA
Nordiazepam	40	2.5
Imipramine	20	7.5
Morphine	20	6.0
D,L-Amphetamine	90	7.0
Benzoylecgonine[a]	30	5.0
11-nor-Δ^8-THC-COOH[b]	10	3.0
Atrazine	10	0.2

[a] A cocaine metabolite.
[b] 11-nor-Δ^8-tetrahydrocannabinol-9-carboxylic acid (a cannabinoid metabolite).

Figure 6 Scheme of the distribution of reactants in the SF mixing system and of the position of the polarizers in the T-format spectrofluorimeter. (Ag) analyte; (F–Ag) tracer; (Ab) antibody; (P_{ex}) excitation polarizer; (P_{em}) emission polarizer; (I_V and I_H) fluorescence intensities measured with the emission polarizer placed parallel and perpendicular, respectively, to the excitation polarizer.

arising from endogenous background interference, which are avoided in the CL heterogeneous format. As in other CL methods, the analyte concentration is usually related to the maximum emission intensity or the integrated light output over a fixed fraction of the total reaction time, although it has also been reported that the precision can be improved by measuring the rate of intensity change over a wide interval after mixing.[46]

A variety of reactions have been evaluated and shown to be suitable for use in CL immunoassay. Indeed, hundreds of reports describing such reactions have appeared in the literature.[47–49] CL immunoassays can be classified into three groups, as follows.

1. Those where the label can be a CL or BL substance, such as luminol or the enzyme luciferase. Typical problems with them include a considerable loss of CL efficiency and enzyme activity, respectively, on linking to other molecules such as antigens or antibodies.
2. Those where the label can be a catalyst or a cofactor for a CL reaction. One case in point is peroxidase, which is a catalyst for the luminol–peroxide reaction, and nicotinamide adenine dinucleotide (NAD), which is a cofactor for the BL reaction catalyzed by bacterial luciferase–oxidoreductase.

3. Products from labels that can be monitored using a luminescent reaction. One example is dehydrogenase enzyme labels that produce the reduced form of nicotinamide adenine dinucleotide (NADH). The product is monitored using the bioluminescent bacterial luciferase–oxidoreductase reaction.

6 AUTOMATION

Similarly to other kinetic determinations, automation has played a crucial role in luminescence-based kinetic determinations by facilitating application to routine analyses. For instance, automatic luminometers for BL determinations are now commercially available and can measure the maximum intensity or integrate the light output over a selection of fixed times. Some such luminometers have been specifically designed for measurement of ATP or nicotinamide adenine dinucleotide phosphate (reduced form) (NAD(P)H). This section briefly reviews the different automatic kinetic approaches based on luminescence detection, namely FI, SF and continuous addition of reagent (CAR).[50,51] Applications of these methods to drug analysis were recently reviewed.[52]

6.1 Flow Injection

Flow injection has proved extremely useful for luminescence-based kinetic determinations. The automated sample handling, controlled sample dispersion and precise time aspects of this approach are distinct advantages.[53] Among FI modes, SF FI[54] and sequential injection[55] are specially useful for kinetic-based determinations. In the SF FI mode, after a preset delay time, the pump is stopped and then re-started once the SF period has elapsed. This allows a selected portion of the dispersed sample zone to be arrested in the observation field of the detector. As physical dispersion virtually ceases when the carrier stream is stopped, the variation of the signal with time reflects the kinetics of the chemical reactions between the mutually dispersed components of the injected sample and carrier stream. This approach allows the reaction rate to be measured as it is not affected by the static background signal from the sample. Figure 7 shows a schematic diagram of the system (a), a portion of the dispersed sample zone (b) and the variation of the signal with time at three different analyte concentrations (c). The system is furnished with a timer (T) that is started when valve S is switched to its injection position.

The SF FI mode differs from the normal SF technique, which is described in the next section, in that (a) sample and reagent are not mixed at a high pressure, (b) the former does not allow fast reactions to be monitored and (c) real-time analyses (e.g. in an enzymatic reaction) are more difficult to accomplish because of the continuous nature of the flow. An attempt at overcoming the pitfalls of this technique was made by developing an automated micro SF continuous apparatus for serial measurements on enzyme reactions.[56] It uses two symmetrically arranged sets of sample injectors (FI system) and stops the carrier stream (SF system), which circulates at a high flow-rate, by means of a high-speed peristaltic pump. Equipped with suitable detectors, the apparatus was used as a real-time analyser for column chromatography.

Sequential injection[55] is a second-generation SF technique based on the sequential aspiration of sample and reagent zones through a selector valve into a holding

Figure 7 (a) Reaction rate measurements based on the SF method are performed in a manifold furnished with a timer, T, which is activated when valve S is turned to the injection position. After a pre-selected delay time, the pump is stopped and then re-started after the SF period has elapsed. This allows a selected portion of the dispersed sample zone (shown schematically in (b)) to be arrested to the observation field of the detector. (c) The resulting peak is composed of the following three sections: continuous flow showing the peak maximum as recorded during the delay period; the reaction rate curve recorded during SF; and the washout tail. Three injections with increasing analyte concentrations are shown, recorded from identical starting points and showing increasing reaction rates R_1, R_2 and R_3. (Reproduced by permission of the Royal Society of Chemistry, from Ruzicka and Christian.[54])

Figure 8 Sequential injection principle. (a) Flow scheme. (b) Structure of the stacked and injected zones. (c) Concentration profiles seen by the detector. (HC) holding coil; (D) detector; (S) sample; (R) reagent; (H) peak height; (I) injection point. (Reproduced by permission of Elsevier, from Ruzicka.[55])

coil, as shown in Figure 8. A stack of well-defined zones is thus obtained. The flow direction is then reversed, and the zones are injected into a reactor and detector. The flow reversal creates a composite zone in which sample and reagent zones penetrate each other. For kinetic determinations, the flow is then stopped and a portion of the composite zone is trapped inside the flow cell of the detector, which allows measurement of the reaction rate.

A procedure for obtaining kinetic data from FI peak profiles by correcting for the effects of dispersion was developed by Chung and Ingle.[57] The method acquires and stores the peak profiles of a nonreacting reference solution and a reacting sample solution. The dispersion coefficients obtained from the reference profile are used to normalize the profile of the sample solution. The utility of this method was demonstrated by adapting a kinetic fluorimetric method for the determination of aluminum with acid alizarin garnet R[58] and using the fixed-time method.

As noted in section 4.1, the shortcomings of batch luminometers can be circumvented by using FI systems. FI CL methods are simplified by reducing the number of reagents that need to be pumped separately to the reaction site, as reagents can be electrochemically produced from passive precursors in the carrier medium. A typical instrumental set-up that was applied to morphine determination[59] is shown in Figure 9. The sample is injected into one flowing stream and the CL reagent flows in the other stream. The two streams meet head-on at a T-piece, inside a light-tight casing, and then flow through a flat coil placed immediately in front of the detector. The coil serves to retain the solution in view of the detector whilst it is emitting most intensely. The system provides very rapid, reproducible mixing and emission intensities, and affords a high throughput.

One other choice in CL analysis is the use of immobilized systems. In this case, the CL intensity depends on both the kinetics of the CL reaction and on the efficiency of mass transfer processes involved in bringing the reactants into contact. Similarly to the use of enzymes, the principal advantages of BL reagents (e.g. firefly or bacterial luciferase) immobilized on solid supports are their reusability, which can significantly reduce reagent costs and improve stability, sensitivity and compatibility with automated continuous flow analyzers.[60] The use of ECL as detection system for LC and FI has given rise to the development of various types of ECL flow cells.[36]

6.2 Stopped-flow

The SF mixing technique is the automatic approach based on kinetic methodology most commonly used when fast reactions are involved. In applying this technique,

Figure 9 Flow injection manifold for morphine determination with chemiluminescence detection. (Reproduced by permission of the Royal Society of Chemistry, from Abbot et al.[59])

two reactants are driven at a high speed by means of two drive syringes through a mixing chamber, the flow of the reactants being abruptly stopped by using a third, stop syringe, and the extent of reaction being monitored by measuring a given property such as the luminescence emission. The most salient features of the SF technique are its ability to mix sample and reagent solutions automatically, the possibility of making measurements shortly after mixing, a high overall precision and minimization of potential interferences. Although this technique is specially suitable for fast reactions (it facilitates the study of the kinetics and mechanisms of these reactions and their use in developing kinetic determination methods), it has also proved useful for developing quantitative methods involving slower reactions as it minimizes reactant manipulation and affords a higher precision than do conventional kinetic approaches. These features make the SF technique particularly attractive to routine laboratories, which require automated instrumentation, high throughputs and the ability to use low solution volumes.[61]

The SF approach shows attractive features when applied to CL monitoring. Thus, mixing is very rapid, the emitting solution may be retained in the measuring cell for whatever time is desired and, unlike the FI approach, the intensity–time curve can be monitored, thus allowing kinetic measurements to be made (see Figure 10). Formation and decay rates of CL have been found to provide better precision and selectivity than conventional parameters such as the peak high intensity or the area under the emission light–time curve.[32] This approach was tested for the first time on the determination of hydrogen peroxide by its classical reaction with luminol catalyzed by cobalt,[32] and has proved useful for other determinations such as penicillins[62] and manganese.[63]

Figure 10 Intensity/time profile obtained in the SF determination of hydrogen peroxide. Zones A and B allow the formation and decay rates, respectively, to be evaluated. (Reproduced by permission of Elsevier, from González-Robledo et al.[32])

The potential of the SF mixing technique in combination with MSRTP was demonstrated by developing a kinetic method for carbaryl determination.[24] Compared with conventional MSRTP, where a phosphorescent system takes a relatively long time to reach equilibrium, the special features of the SF mixing technique allow the fast acquisition of kinetic data and provide a very simple means of accomplishing automation in phosphorescence routine analyses. This approach also avoids the two major constraints of solid-surface room-temperature phosphorimetry (SSRTP), namely the presence of a background signal from the solid supports used, which affects detection limits, and the critical preparation and measurement requirements, which influence the precision of the analytical results.

The term ''SF-fluoroimmunoassay'' has been applied to the use of this mixing technique in homogeneous determinations based on immunochemical reactions. This approach was used for the determination of the pesticide 2,4-dichlorophenoxyacetic acid in fruit juice samples.[64] The system was characterized by the very fast initial rate of the antigen–antibody reaction and the fluorescence quenching of the tracer (fluorescein-labeled pesticide) upon reaction with the antibody. The signal obtained at equilibrium was severely affected by the presence of the sample matrix, which is very common in fluorescence quenching methods, since the static signal is highly sensitive to the environmental conditions. This shortcoming, however, was avoided by measuring the initial rate of the system. SF-immunoassay was also applied to the development of a direct homogeneous method for the determination of coproporphyrin[65] in urine, based on the native fluorescence of this porphyrin and the use of the initial rate of the antigen–antibody reaction as analytical parameter, which was obtained by measuring the decrease in fluorescence intensity with time. The method is simpler than the competitive immunoassay, where a tracer is used, and avoids the separation step required in heterogeneous immunoassay.

6.3 Continuous Addition of Reagent

The CAR technique is a fairly recently reported open system approach based on the continuous addition of a reagent solution, at a constant rate, to another solution containing the species to be determined.[66] Analytical data obtained from second-order reactions are processed by using a mathematical treatment that relates kinetic parameters with the experimental variables. This treatment also allows the second-order rate constant of the system to be determined. The chief advantages of this technique are that the kinetic response curve can be readily obtained from both slow and fast reactions (for which the first-order condition is commonly used)

with straightforward instrumentation since the reaction is made second-order.[67] The typical instrumental set-up consists of: (1) an addition unit with an autoburette, a magnetic stirrer and a thermostated vessel (the reaction cell); (2) a detection system such as a luminescence detector; and (3) a computer unit for data acquisition and processing. The second-order kinetic profile of the signal versus time (or volume added) response includes a straight portion, the slope of which is proportional to the analyte concentration (maximum-rate method); this is equivalent to the initial-rate method used for pseudo first-order kinetic responses in the SF technique.

The CAR technique has been applied to the fluorimetric determination of morphine in urine[68] using the classical oxidative dimerization of this drug by alkaline potassium hexacyanoferrate(III) to form a highly fluorescent dimer (pseudomorphine). The conventional method poses problems arising from instability of the reaction products and undesirable interactions between them and the excess of reagent, which quench the fluorescence of pseudomorphine. However, the CAR technique avoids these problems since the reagent is continuously added from the autoburette, thereby increasing the fluorescence intensity.

The adaptation of the CAR technique to CL reactions has allowed some problems of the analytical application of these reactions to be solved. Thus, this approach is an effective means for suppressing background emission in peroxyoxalate CL reactions, which is ascribed to the formation and decomposition of CL reaction intermediates. This ability arises from the special way in which the sample and reagent are mixed in the CAR technique, in addition to its kinetic connotations. The analytical utility of the combination of the CAR technique with CL reactions has been demonstrated by applying the *bis*(2,4,6-trichlorophenyl)oxalate (TCPO)/hydrogen peroxide system to the determination of acepromazine in horse plasma samples.[69] The CAR technique has also been used as an effective means for enhancing the performance of energy transfer CL-based determinations involving the use of a sensitizer. Thus, the reaction between tertiary aliphatic amines and sodium hypochlorite in an alkaline medium containing fluorescein as sensitizer has been used to determine trimethylamine in fish samples.[70]

7 SIMULTANEOUS DETERMINATIONS

Although classical differential kinetic methods have been applied in simultaneous determinations with luminescent detection, recent investigations have chiefly been aimed at accomplishing mathematical discrimination by using complex chemometric methods or instrumental discrimination by use of multidetection devices. Procedures that exploit both kinetic and spectral differences have thus been developed. Also, automation is a general trend in the latest simultaneous determinations.

Among classical approaches, the proportional-equation method has been applied in conjunction with the SF mixing technique to the simultaneous determination of salicylic acid and diflunisal[30] by the combined use of kinetic and equilibrium measurements. The similar structures of these compounds result in mutual interferences with the determination of each other. Thus, the corresponding ternary anionic chelates formed with terbium(III) and ethylenediaminetetraacetic acid (EDTA) in an alkaline medium exhibit the same initial rate and equilibrium luminescence intensity. However, the presence of cetyltrimethylammonium bromide (CTAB) increases both parameters to a different extent, which has been ascribed to the formation of ion-association complexes between CTAB and the ternary anionic chelates formed by salicylate and diflunisal with terbium(III) and EDTA in the alkaline medium. Epinephrine and norepinephrine were simultaneously determined in urine[71] by using the trihydroxyindole method, which was simplified by implementing the SF technique.

Micellar media provide additional advantages that have scarcely been explored in simultaneous kinetic analyses with luminescence detection. Micelles can alter the apparent rate constant of two or more species with similar structure, interacting with a common reagent by both altering their intrinsic reactivity and, more generally, binding to a different extent to analytes. This effect has been applied to the simultaneous determination of pyridoxal and pyridoxal-5′-phosphate by using their cyanide-catalyzed oxidation in the presence of CTAB micelles.[72] The initial rate and the fluorescence intensity increment of these systems were used as analytical parameters and data were processed by using a system of two equations which was solved by multiple linear regression.

The logarithmic extrapolation method was applied to the simultaneous determination of thiamine and its pyrophosphate ester, cocarboxylase,[73] using the differential oxidation rate of these compounds with mercury(II).

The T-format spectrofluorimeter described above, furnished with an SF module, was used for the direct resolution of a mixture of two drugs, neomycin and promethazine (an antimicrobial and an antihistamine respectively), which are found together in some pharmaceutical preparations.[74] This was the first reported application of kinetic methodology based on reaction-rate measurements to a simultaneous fluorimetric determination using a dual-channel instrument. As the T-format configuration has two emission paths symmetrically

arranged on both sides of the sample compartment, it allows one to simultaneously monitor the development of the reaction of neomycin with *o*-phthaladehyde in the presence of *N*-acetylcysteine and the oxidation of promethazine by dissolved oxygen without the need for an oxidant such as hydrogen peroxide, since both reaction products have similar excitation wavelengths but different emission wavelengths. The absence of overlap in the emission maxima allows one to obtain kinetic data from each individual system, even if both possess similar rate constants and their reactions are fast. In this instance, both systems exhibited a disparate kinetic behavior: whereas neomycin reached equilibrium within only 3–4 s, promethazine took about 40 s. However, their high initial rates justified the use of the SF mixing technique. The method allowed the resolution of mixtures containing neomycin and promethazine in ratios between 8 : 1 and 1 : 9, and was applied to pharmaceutical analyses.

This approach was also applied to the simultaneous determination of the antibiotics ampicillin and tetracycline in milk.[75] The determination of ampicillin was based on its hydrolysis with penicillinase and reaction with mercuric chloride; that of tetracycline relied on the intramolecular energy transfer from the analyte to europium ions in the presence of thenoyltrifluoracetone. Owing to the differential kinetic behaviour of the two chemical systems involved, kinetic and equilibrium measurements were carried out to obtain quantitative data for penicillin and tetracycline, respectively.

The flexibility and simplicity of the FI approach has been exploited in the development of a number of differential kinetic methods. Thus, the differential catalytic activity of manganese(II) and iron(III) ions on the oxidation of salicylaldehyde thiosemicarbazone by hydrogen peroxide has been used for the simultaneous determination of these ions[76] with an FI configuration that splits the sample into two channels with different geometric and hydrodynamic characteristics and then recombines both channels prior to the detector. The differential residence times for the sample portions result in two peaks in which the contribution of each ion to the formation of the oxidation product is different.

Regarding chemometric methods, the Kalman filtering algorithm has been applied to the simultaneous time-resolved determination of antibiotics such as tetracyclines[77] and anthracyclines[78] in solution by formation of luminescent chelates with europium(III). An optosensing FI manifold involving a flow cell packed with a nonionic resin was used in both instances. Each determination utilized the differences in decay rates of the chelates adsorbed onto the resin and the Kalman filter to process decay data.

Artificial neural networks[79] have been used in combination with the CAR technique to resolve phenothiazine mixtures[80] by using CL reactions with a peroxyoxalate derivative. The CAR technique suppresses background emission from these CL reactions. The chemometric method allows the simultaneous determination of trimeprazine and methotrimeprazine, even though both compounds exhibited a similar kinetic behavior and synergism. Luminol CL induced by hexacyanoferrate(III) and enhanced by phenolic acids was used for the simultaneous determination of protocatechuic and caffeic acids.[81] The synergistic effects present required the use of surface response and least-squares matrix methodologies.

Kinetic fluorescence detection has been utilized for the determination of glycine and glutamine (previously partially separated on a thin-layer chromatography (TLC) plate).[82] The formation and decay of the intermediate fluorescent products formed between these species and *o*-phthalaldehyde was monitored with a charged-coupled device camera by taking sequential images of the TLC plate. A direct trilinear decomposition method was used to analyze the resulting third-order data, which consisted of fluorescence intensities as a function of elution distance, reaction time and sample number.

Table 2 Selected examples of luminescence-based kinetic determinations

Analytes	Luminescence process	Remarks	Refs.
Enzymes and enzymatic substrates	F	Many sensitive methods	14, 15
Inorganic ions	F	Catalysis, activation or inhibition	5, 6, 16, 17, 76
	CL	Catalysis, activation or inhibition	25, 26, 63
	P	Temporal resolution	36
Amino acids	F	Kalman filter	22
	F	Simultaneous determinations	82
Proteins	F	Long wavelength	19, 20
Pharmaceuticals	F	Immunoassay	43
	LSL	Simultaneous determinations	30, 75, 77, 78
	CL	SF	62
	F	ANN	80
Abused drugs	F	Immunoassay	44
	CL	FI	59
	F	CAR	68
Pesticides	F	Immunoassay	41, 45, 64
	P	MSRTP	24

F, fluorescence; P, phosphorescence; LSL, lanthanide-sensitized luminescence; ANN, artificial neural networks.

8 FINAL REMARKS

The analytical interest of luminescence-based kinetic determinations is the result of the high sensitivity and versatility of luminescence techniques together with the temporal discrimination of the analytical signal that is obtained by using kinetic methodology. Table 2 summarizes some selected examples of these determinations, which shows the wide application field of this approach.

LIST OF SYMBOLS

k_F	Fluorescence Rate Constant
k_I	Rate Constant for Internal Conversion for Lowest Excited Singlet State
k_{IS}	Rate Constant for Intersystem Crossing
k_M	Rate Constant for Intersystem Crossing between Lowest Triplet State and Ground State
k_P	Phosphorescence Rate Constant
k_Q	Rate Constant for Biomolecular Quenching
k_q	Rate Constant for Relaxation Processes other than Phosphorescence Decay
P	Degree of Polarization
ϕ_F	Fluorescence Quantum Yield
ϕ_P	Phosphorescence Quantum Yield
ϕ_T	Triplet Formation Quantum Yield
$[Q]$	Concentration of Quencher
τ_F	Observed Fluorescence Lifetime
τ_{F0}	Intrinsic Fluorescence Lifetime
τ_P	Observed Phosphorescence Lifetime
τ_{P0}	Intrinsic Phosphorescence Lifetime

ABBREVIATIONS AND ACRONYMS

ADC	Analog to Digital Converter
BL	Bioluminescence
CAR	Continuous Addition of Reagent
CL	Chemiluminescence
CRT	Cathode-ray Tube Screen
CTAB	Cetyltrimethylammonium Bromide
ECL	Electrogenerated Chemiluminescence
EDTA	Ethylenediaminetetraacetic Acid
FI	Flow Injection
FMN	Flavin Mononucleotide
FPIA	Fluorescence Polarization Immunoassay
LC	Liquid Chromatography
MSRTP	Micelle-stabilized Room-temperature Phosphorimetry
NAD	Nicotinamide Adenine Dinucleotide
NADH	Reduced Form of Nicotinamide Adenine Dinucleotide
NAD(P)H	Nicotinamide Adenine Dinucleotide Phosphate (Reduced Form)
PMT	Photomultiplier Tube
PT	Reference Vacuum Phototube
SDS	Sodium Dodecyl Sulfate
SF	Stopped-flow
SSRTP	Solid-surface Room-temperature Phosphorimetry
TCPO	*bis*(2,4,6-Trichlorophenyl)oxalate
TLC	Thin-layer Chromatography

Analytical procedures in which the measurement step (chemical, physical or physicochemical) is influenced by a transient (kinetic) process, can strictly be classified as kinetic method. Thus, the majority of modern analytical methods (continuous-flow, time-resolved fluorimetric and chromatographic methods, among others) are kinetic in nature. Nevertheless, the term ''kinetic method'', for historical reasons, is incorrectly limited to methods based on direct or indirect measurements of the rate of a chemical reaction, which should be classified as ''reaction-rate methods''. Analytical methods based on signal measurements made under dynamic conditions compete in efficiency with static and equilibrium measurements. The growing development of kinetic methods is due to the need for quantification of microamounts of substances, increasing knowledge of reaction mechanisms, and breakthroughs in instrumentation and data handling and interpretation. The most popular classification of kinetic methods of analysis is based on the chemistry of reactions employed and distinguishes between catalytic (nonenzymatic, enzymatic and electrochemical), and noncatalytic methods. The latter are further categorized into those used to determine a single species or several components in mixtures (differential reaction-rate methods). This article deals with kinetic methods for the determination of single noncatalytic species. Although the majority of kinetic-based determinations depend on catalytic systems, some analytical applications using the rate of uncatalyzed reactions are of analytical interest, mainly those involving organic chemical species. Advances in instrumentation: (1) improved signal detection, (2) resolving of problems arising from time measurements especially in fast processes, and (3) availability of automated mixing devices and data processing (error-compensated methods, curve-fitting and predictive approaches) establish noncatalytic methods as powerful alternatives to equilibrium methods. The main field of application of noncatalytic reactions is organic analysis, unlike catalytic reactions where a metal ion usually acts as the catalyst.

1 THEORETICAL BACKGROUND[1–3]

1.1 Reaction Rate and Kinetic Equation

The kinetic determination of a noncatalytic species is based on the monitoring of its reaction rate by direct or indirect measurements of changes in the reactant or product concentration. The reaction rate is defined as the change in concentration of one of the components (reactant consumed or product formed) of the chemical system per unit time. From a practical analytical viewpoint, methods using uncatalyzed reaction rates are limited to those following pseudo-zero-order, first-order, and pseudo-first-order kinetics, since most of the chemical systems used involve bimolecular reactions and orders higher than two are rare and of no analytical applicability.

For a straightforward reaction of the type $A + R \longrightarrow P$, where A is the species of analytical interest (analyte), R is the added reagent and P is the product, the general

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

differential rate expression at time t will be given by Equation (1)

$$\text{rate} = \frac{\text{d[P]}}{\text{d}t} = -\frac{\text{d[A]}}{\text{d}t} = -\frac{\text{d[R]}}{\text{d}t} \quad (1)$$

in which the derivatives of [A] and [R] are negative because both species are consumed as the reaction proceeds. The reaction rate at time t depends on the concentrations of all the species involved and the pertinent kinetic equation can be derived as Equation (2)

$$\text{rate} = \frac{\text{d[P]}}{\text{d}t} = k[\text{A}][\text{R}] \quad (2)$$

where k is defined as the rate constant and expresses the reaction rate per unit concentration of the reactants. The reaction order is defined as the sum of the exponents of [A] and [R] in Equation (2), known as partial reaction orders; thus, the above reaction is second order.

In the case of one of the reactants (e.g. R) being present in a large excess (over 50-fold) relative to the other, then its concentration remains practically constant and can be included in the term k in Equation (2) and the reaction is considered to be pseudo-first-order in A or pseudo-zero-order in R, i.e. Equation (3)

$$\text{rate} = \frac{\text{d[P]}}{\text{d}t} = k_{\text{A}}[\text{A}] \quad (3)$$

where k_{A} is the pseudo-first-order rate constant. The experimental parameters for most kinetic methods are adjusted so that pseudo-first-order reaction conditions are established.

Instead of the concentrations in Equation (1) any measurable quantity of analytical signal (S) directly proportional to concentration (absorbance, fluorescence, etc.) can be used. Special equations are derived when the signal is not linearly related to the concentration (e.g. potentiometric measurements). The changes in reactant or product concentrations as a function of time can be monitored physically or chemically. Physicochemical techniques (spectrophotometry, fluorimetry, potentiometry, etc.) are preferable for reaction monitoring and provide a signal versus time curve. In the majority of kinetic methods only the initial section of the curve is used, i.e. when the reaction has only proceeded by 1–3%. This section is usually linear with a slope proportional to the analyte concentration (initial-rate approach).

1.2 Determination of Reaction Orders and Rate Constants

The kinetic study of a reaction is performed using the so-called *continuous* (in situ) or *discontinuous* (batch) approach. In a continuous kinetic study, an analytical parameter (signal) (absorbance, potential, fluorescence, etc.) related to the changing concentration of a reactant or product is continuously monitored by means of an analytical instrument connected to a recorder, printer or microcomputer. In contrast, in a discontinuous study (usually used for rather slow reactions and processes), aliquots of the reacting mixture are removed by the analyst at preselected time intervals and analyzed immediately or all together in a batch mode after quenching (killing) the reaction at the time of sampling. The analytical parameter – time curves can be used for the determination of reaction orders and rate constants, usually after transformation to concentration – time curves.

1.2.1 Determination of Reaction Order

The order of a reaction (or process) may be determined by the following methods.

1.2.1.1 Substitution Method The concentration data obtained in a kinetic study are substituted in the integrated form of the equations that describe the various reaction orders and the k values are calculated. The reaction is considered to be of that order that follows the equation that gives constant k values within the limits of experimental error.

A reaction order of 0 gives an integrated rate equation:

$$x = kt$$

and a half-life equation:

$$t_{1/2} = \frac{\alpha}{2k}$$

A reaction order of 1 gives an integrated rate equation:

$$\log \frac{\alpha}{(\alpha - x)} = \frac{k}{2.303}t$$

and a half-life equation:

$$t_{1/2} = \frac{0.693}{k}$$

A reaction order of 2 for [2A $\longrightarrow$ P] or [A + B $\longrightarrow$ P] with equal concentrations gives an integrated rate equation:

$$\frac{x}{\alpha(\alpha - x)} = kt$$

and a half-life equation:

$$t_{1/2} = \frac{1}{\alpha k}$$

A reaction order of 2 for [A + B $\longrightarrow$ P] with unequal concentrations gives an integrated rate equation:

$$\log \frac{\beta(\alpha - x)}{\alpha(\beta - x)} = \frac{(\alpha - \beta)k}{2.303}t$$

where α and β are the initial concentrations of reactants A and B, respectively, and x is the concentration of each species reacting in a time t.

1.2.1.2 Fitting (Graphical) Method Plots of a function of concentration C of the reactant versus t can also be used to ascertain the reaction order. Thus, if a plot of C versus t results in a straight line, the reaction is zero order. The reaction is first order if the plot of $\log C$ versus t yields a straight line and it is second-order if a plot of $1/C$ versus t results in a straight line (in the case of equal initial concentrations).

1.2.1.3 Half-life Method As shown above, the half-life is proportional to the quantity $1/(\alpha^{n-1})$, in which n is the order of the reaction (for a second-order reaction we assume that $\alpha = \beta$). Thus, if the same reaction is run at different initial concentrations, α_1 and α_2, the half-lives $t_{1/2(1)}$ and $t_{1/2(2)}$ are related according to Equation (4)

$$\frac{t_{1/2(1)}}{t_{1/2(2)}} = \left(\frac{\alpha_2}{\alpha_1}\right)^{n-1} \tag{4}$$

By taking the logarithms and rearranging we have Equation (5)

$$n = \frac{\log[t_{1/2(1)}/t_{1/2(2)}]}{\log(\alpha_2/\alpha_1)} + 1 \tag{5}$$

The half-lives are obtained by plotting C versus t at two different initial concentrations and reading the time at $\alpha_1/2$ and $\alpha_2/2$. By substituting these values and the initial concentrations in Equation (5), the order n is obtained directly. Alternatively, two concentrations during a single run may be taken as α_1 and α_2 and the half-lives determined in terms of α_1 and α_2.

1.2.1.4 Initial Reaction Rate (van't Hoff) Method In the previous methods 1–3 (sections 1.2.1.1–1.2.1.3), the reaction must be completed to a large extent. The so-called initial reaction-rate method consists of measuring the initial reaction rates v_0 for different initial concentrations of a reactant, while the initial concentrations of the other reactants are held constant. From Equation (6)

$$v = \text{rate} = \frac{\mathrm{d[P]}}{\mathrm{d}t} = k[\mathrm{A}]^a[\mathrm{B}]^b[\mathrm{C}]^c \tag{6}$$

it is concluded (since B and C are constant) that Equation (7) follows

$$\log v_0 = \log(\mathrm{d[P]}/\mathrm{d}t)_0 = \text{constant} + a \log [\mathrm{A}]_0 \tag{7}$$

The partial reaction order a, with respect to A, is obtained from the slope of the plot of the logarithms of initial rates versus the logarithms of the initial concentrations. In a similar way the partial reaction orders with respect to B and C can be determined by two further sets of kinetic runs.

In the above methods, instead of the concentration of the species of interest, an analytical parameter (signal) linearly related to the concentration can be used in calculations, since the units cancel.

1.2.2 Determination of Rate Constants

Once the order of the reaction has been determined, calculation of the rate constant can easily be achieved using the above integrated equations by substitution or least squares regression plotting. In the above initial reaction rate method, the antilogarithm of the constant term of Equation (7), which is referred to as the apparent or observed rate constant, k_{obs}, is equal to $k[\mathrm{B}]_0^b[\mathrm{C}]_0^c$ (Equation 6). Thus, the value of k is easily calculated from k_{obs} values using the known initial concentrations of B and C, and the already estimated partial orders b and c.

Since the majority of the analytical reactions used in kinetic analysis are first- or pseudo-first-order, two commonly used methods for the determination of first-order reaction rate constants from experimental (signal) data are presented.

1.2.2.1 Infinite-time Method The course of the reaction is followed by measuring some signal S, which is linearly related to the concentration of one of the reactants or the product. The signal varies with time according to Equation (8)

$$(S_\infty - S) = (S_\infty - S_0)\mathrm{e}^{-kt} \tag{8}$$

in which S_0, S, and S_∞ are the values of the measured signal at $t = 0$, t, and $t = \infty$, respectively. It is obvious that a plot of $\ln[(S_\infty - S)/(S_\infty - S_0)]$ versus t will be a straight line with a slope equal to $-k$ (or $-k_{\text{obs}}$). This method requires the completion of the reaction.

1.2.2.2 Guggenheim Method This method does not require completion of the reaction. If the readings of the analytical signal, $S_1, S_2, \ldots, S_i$ are made at times $t_1, t_2, \ldots, t_i$ and a second series of readings $S_1', S_2', \ldots, S_i'$ is made at the corresponding times $t_1 + \Delta t, t_2 + \Delta t, \ldots, t_i + \Delta t$ (where Δt is a constant of magnitude of the order of one half-life) then Equation (9) follows

$$(S_\infty - S_i') = (S_\infty - S_0)\mathrm{e}^{-kt_i} \tag{9}$$

and Equation (10)

$$(S_\infty - S_i') = (S_\infty - S_0)\mathrm{e}^{-k(t_i+\Delta t)} \tag{10}$$

After subtracting Equation (10) from Equation (9), obtaining the logarithms and assuming that S_∞, S_0, and Δt are constants, we have Equation (11)

$$\ln|P_i' - P_i| = \text{constant} - kt_i \tag{11}$$

from which by plotting the left-hand function versus t_i a straight line is obtained with a slope equal to $-k$ (or $-k_{obs}$). For the application of the Guggenheim method the reaction should obey first-order kinetics over at least two half-life periods.

The partial order in a given reactant will be unity if a plot of initial rate versus reactant concentration is a straight line; in fact, at $n = 1$, Equation (3) is representative of a straight line of zero intercept.

2 DETERMINATION OF A SINGLE COMPONENT – PRINCIPLES OF METHODS AND TECHNIQUES[1–8]

The determination of the analyte A based on the second-order reaction described by the rate Equation (1) can be performed under two limiting conditions: (1) in the case of R being in large excess (over a 50-fold) relative to the analyte (A), then the reaction will proceed under pseudo-first-order in respect to A or (2) in the case of concentration of R being equal to or less than 50 times the concentration of A, the reaction will proceed under second-order conditions.

The various approaches used in the determination of a single noncatalytic species are shown in Table 1 and discussed in detail below.

2.1 Pseudo-first-order Conditions

The general differential rate expression of a reaction under pseudo-first-order conditions in respect to the analyte, A, is Equation (12):

$$\text{rate} = -\frac{\mathrm{d[A]}}{\mathrm{d}t} = \frac{\mathrm{d[P]}}{\mathrm{d}t} = k[\mathrm{A}][\mathrm{R}]_0 = k_{\mathrm{A}}[\mathrm{A}] \quad (12)$$

where $k_{\mathrm{A}} = k[\mathrm{R}]_0$. Equation (12) is normally the basis for the kinetic determination of A under pseudo-first-order conditions.

Table 1 Analytical approaches used in kinetic determinations of single noncatalytic species

Pseudo-first-order conditions
Initial rate approach
Fixed-time approach
Variable-time approach
Signal-stat approach
Second-order conditions
Identical reactant concentrations
Unequal reactant concentrations
Multipoint approaches
Curve-fitting approach
Predictive approach
Error-compensated approach

In the case of initial-rate approach, the rate expression (Equation 12) can be written in incremental form as Equation (13):

$$\text{rate} = -\frac{\Delta[\mathrm{A}]}{\Delta t} = k_{\mathrm{A}}[\mathrm{A}]_0 \quad (13)$$

from which the concentration of the analyte A can readily be calculated. In this approach, the rate of signal change is measured (or computed) and related to the analyte concentration. Assuming that the analyte is the rate determining reactant (R is in excess), the relationship can be represented as Equation (14)

$$\text{rate} = \frac{\Delta S}{\Delta t} = bk[\mathrm{A}]_0 \quad (14)$$

where b is the sensitivity factor. Calibration standards are usually used to obtain a calibration constant representing the proportionality factor, bk. In such procedures, changes in any variable (e.g. temperature, pH) that would affect the rate constant would produce an error in the determined concentration.

The principles of fixed-time and variable-time approaches are based on Equation (15) which is the exponential expression of Equation (12):

$$\text{rate} = -\frac{\mathrm{d[A]}}{\mathrm{d}t} = k_{\mathrm{A}}[\mathrm{A}]_0 \exp(-kt) \quad (15)$$

Assuming that $t_2 = t_1 + \Delta t$, the integration of Equation (15) over an interval $t_2 - t_1$ results in Equation (16)

$$[\mathrm{A}]_0 = \frac{-\Delta[\mathrm{A}]}{\exp(-k_{\mathrm{A}}t_1)[1 - \exp(-k_{\mathrm{A}}\Delta t)]} \quad (16)$$

In the fixed-time approach t_1 and Δt are kept constant, thus, as stated from Equation (16) a linear relationship exists between $\Delta[\mathrm{A}]$ and $[\mathrm{A}]_0$. In a one-point/fixed-time approach, the detector signal, S_t, is measured at some fixed point in time after the reaction (process) is initiated. In such procedures applied to first-order reactions, the background signal, S_0, is assumed to be zero and analyte concentration is determined from a single proportionality of the form (Equation 17)

$$[\mathrm{A}]_0 = \frac{S_t}{b[1 - \exp(-k_{\mathrm{A}}t)]} \quad (17)$$

where b is the sensitivity factor. The calibration constant, $\{1/b[1 - \exp(-k_{\mathrm{A}}t)]\}$ is evaluated by calibration standards or calibration plots. The one-point option cannot compensate for background (blank) signals and it cannot detect unexpected changes in kinetic behavior. Any change in variables that would affect the rate constant would also affect the calibration constant and computed concentration. The one-point/fixed-time approach

is seldom used now because it does not compensate for changing backgrounds.

The two-point/fixed time option is perhaps the most widely used approach for kinetic determinations. In this approach, two signal values, S_1 and S_2, are measured at two points in time, t_1 and t_2, and the difference, $\Delta S_t = S_1 - S_2$, is used to compute the concentration. The mathematical description for a first-order process is easily shown to be Equation (18)

$$[A]_0 = \frac{\Delta S_\infty}{b} = \frac{\Delta S_t}{b[\exp(-k_A t_1) - \exp(-k_A t_2)]} \qquad (18)$$

In the most common applications of this approach, the calibration factor in the denominator of the term at the far right-hand side of the expression is determined by using calibration standards. This option compensates for background signals but, like the one-point option, cannot detect unexpected changes in kinetic behavior.

In the variable-time approach the quantity $\Delta[A]$ is kept constant. According to Equation (16) Δt and t_1 depend on $[A]_0$, therefore the analyte concentration $[A]_0$ under determination will never be linearly related to $1/\Delta t$. In this situation the error will be minimized if $[A]_1$ is almost equal to $[A]_0$ and therefore $\exp(-k_A t_1) \rightarrow 1$ and at short reaction times (small $\Delta[A]$ and $\Delta t \rightarrow 0$) Equation (16) can be linearized since $[1 - \exp(-k_A \Delta t)]$ can be simplified to $k\Delta t$ by expanding the exponential function as a Maclaurin series. In this option, the measurement objective is the time interval, Δt, required for the reaction (process) to proceed to a predetermined extent.

In the one-point/variable-time approach the quantity measured is the time interval between the start of a reaction and some predetermined point in the reaction, usually completion. An early example of this option is the so-called ''stop-watch method''.

In the two-point/variable-time approach, the measurement objective is the time interval between two predetermined signal values. The time interval is used to compute concentration. This option has some interesting features and has been used in automated kinetic potentiometric methods using a double switch system. A physicochemical analog involves a flow-injection (FI) approach in which the measured quantity is the time required for the detector signal to change between two predetermined points on a response profile (FI pseudo titrations). A plot of Δt versus $\log [A]_0$ is linear.

In the above approaches, knowledge of the relationship between concentration and the detector signal is not required and the dynamic range can be extended by control of reagent concentration.

In the signal-stat approach, the detector signal is used to indicate when a property (e.g. pH) has changed outside some predermined narrow limits and a reagent (e.g. acid or base) is added to return the property to within the desired limits. The quantity of reagent needed to maintain the measured property within the desired limits is measured and used to compute the analyte concentration. Therefore, the time-dependent addition of reagent reflects the time course of the reaction. Usually multiple additions of reagent are required so that a multiple response curve is available. The most common version of this approach is the pH-stat option but the concept should be applicable to the control of any reactant.

In conclusion, the fixed-time approach ensures wider dynamic concentration ranges than does the variable-time approach for first- or pseudo-first-order conditions.

2.2 Second-order Conditions

The rate of a reaction under second-order conditions is dependent on the concentrations of two reactants. The expression for the reaction rate is Equation (19)

$$\text{rate} = -\frac{d[A]}{dt} = -\frac{d[R]}{dt} = \frac{d[P]}{dt} = k[A][R] \qquad (19)$$

In the case of equal concentrations of the two reactants, ($[A]_0 = [B]_0$), Equation (19) becomes Equation (20):

$$\text{rate} = -\frac{d[A]}{dt} = k[A]^2 \qquad (20)$$

Integration of Equation (20) in the time interval zero and t results in the linear expression Equation (21):

$$\frac{1}{[A]_t} = \frac{1}{[A]_0} + kt \qquad (21)$$

from which the analyte concentration $[A]_0$ can be estimated directly.

In the case of an analytical reaction under second-order conditions in which the concentrations of the two reactants are different, integration of Equation (19) between $t_1 = 0$ and $t_2 = t$ results in the general second-order integrated rate expression (Equation 22):

$$\ln \frac{[R]_t}{[A]_t} = \ln \frac{[R]_0}{[A]_0} + ([R]_0 - [A]_0)kt \qquad (22)$$

A plot of the left-hand term $\ln([R]_t/[A]_t)$ versus time will be linear and the analyte concentration $[A]_0$ can be readily calculated from the intercept and the known value of $[R]_0$.

2.3 Multipoint Approaches

The wide availability of computers with high processing power which usually are used on-line with the analytical instruments of kinetic analysis has promoted the development of various powerful approaches based

on the efficient use of the full analytical information from the reaction curve. These include a curve-fitting approach, a predictive approach and an error-compensated approach.

A curve-fitting approach computes modified signals in order to obtain the best fit for a mathematical model describing the transient process. The least-square procedure is widely used for this purpose.

A predictive approach takes advantage of a large number of experimental data to calculate the best estimate for the signal change to be expected if the reaction system were allowed to reach equilibrium (S_∞), using linear or nonlinear least-squares or the Kalman filter. The object of the curve-fitting process would be to obtain best-fit values of S_0, ΔS_∞, and the rate constant, k. Thus, in a single data-processing step, it is possible to compensate intrinsically for variables that affect rate constants.

An error-compensated approach minimizes the marked dependence of the transient signal of the reaction system from experimental variables. Various mathematical algorithms or simultaneous measurements of analytical signals and the variable(s) affecting the system are used in order to establish pertinent corrections.

2.4 Techniques of Mixing and Monitoring

Kinetic methods are performed using instruments of various complexity, from conventional simple systems such as photometers, fluorimeters or potentiometers to highly sophisticated fully automated systems, capable of sample aliquoting, transferring to the detector, signal collecting and manipulating, and processing the results obtained.

Depending on the type of system concerned, several techniques are used for mixing of the reactants to start the analytical reaction.

2.4.1 Conventional Simple Techniques

Slow chemical reactions can be followed using simple spectrophotometric, fluorimetric or potentiometric systems, usually equipped with thermostatted observation cells, and manual mixing and/or magnetic or mechanical stirring.

2.4.2 Stopped-flow Technique

In the stopped-flow (SF) technique a prepared sample solution is mixed rapidly and efficiently with a prepared reagent solution by means of two driving syringes that are actuated manually or by a pneumatic device, through a mixing-chamber into a flow-cell which can also serve as the observation cell. The flow is stopped abruptly by using a third stopped syringe and the analytical signal (usually absorbance or fluorescence) is then recorded as a function of time. This technique is ideal for performing fast reactions with half-lives of a few milliseconds to several seconds. Its performance depends mainly on the dead time (mixing time).

2.4.3 Flow-injection technique

Flow-injection analysis (FIA) has been defined as ''information gathering from a concentration gradient formed from the injected, well-defined zone of a fluid, dispersed into a continuous unsegmented stream of a carrier''. Therefore, all chemical assays performed by FIA can be said inherently and necessarily to entail the utilization of chemical kinetics. Under FIA conditions it is possible to utilize masks which operate on a time-based mode, taking advantages of the differences in kinetic rates between the mask and the interferent or analyte. FIA can operate in a continuous-flow, SF, recycle flow or reversal flow mode. Reactions producing unstable intermediates can be easily adapted in the FIA technique.

In the continuous-flow mode a signal peak is obtained after a preselected time interval (fixed-time approach). If an external mixer is used a wide signal peak is obtained capable of being used in the two-point/variable-time approach. In the SF mode (FI/SF) the reacting mixture is stopped in the detector cell at time t_1 and the signal is monitored during a Δt time interval (reaction rate or slope approach). In the recycle flow mode, as denoted by its name, the reacting plug is passed several times through the flow detector in the same direction providing a multipeak response whose envelope represents the profile of the kinetic curve. In the reversal flow mode, the reacting plug is also passed several times through the flow detector but alternately in opposite directions, which provides a response similar to that of the recycle flow mode.

2.4.4 Continuous Addition of Reagents Technique

The continuous addition of reagents (CAR) technique is based on the continuous addition at a constant rate of one of the reaction components (usually the reagent) in the reaction cell equipped with a stirring device. The reaction curve (absorbance or fluorescence as function of time) is recorded simultaneously with the aid of an automated computer-controlled system.

2.4.5 Stat Technique

This technique, which is suitable for slow reactions, is based on the addition of microamounts of a reactant to the reaction cell at a known rate such that an analytical

parameter of the monitored reaction (pH, absorbance, luminescence, etc.) is maintained constant. Any deviation from this state because of the reaction processing is immediately compensated for by automatically adding an extra amount of the reactant. The rate of addition is used to estimate the reaction rate.

2.4.6 Centrifugal Mixing

This technique is used in parallel fast analyzers. Microvolumes of samples and reagent(s) are added in microwells on a removable rotating disk. The disk is placed in a centrifuge rotor. When the rotor spins, mixing is induced by the action of the centrifugal force, which finally displaces the mixed solution into the observation cell. The technique provides a great number of data during the observation time.

2.5 Detection Systems

The course of a reaction can be monitored by chemical or visual means, but mainly by instruments (photometric, fluorimetric, chemiluminometric, electroanalytical devices). A large number of reactions involve substances that absorb in the near-ultraviolet or visible region. Rapid scanning spectrometry (vidicon image detector, photodiode array) offers an attractive potential for kinetic methods of analysis. Ion selective electrodes (ISEs) are of special use in potentiometric techniques as applied to kinetic analysis on account of their usually high sensitivity to concentration changes and the freedom from optical interferences.

3 REACTION TYPES[1,6]

The various reactions used in kinetic-based noncatalytic determinations of single species can be categorized into several groups, which are described in detail below.

3.1 Complexation Reactions

This group includes both formation and substitution reactions, mainly applied to inorganic analytes.

3.1.1 Substitution Reactions

Kinetic methods based on substitution reactions involve either a ligand or a metal displacement from a starting complex:

- Ligand substitution reaction $ML_1 + L_2 \longrightarrow ML_2 + L_1$
- Metal substitution reaction $M_1L + M_2 \longrightarrow M_2L + M_1$

The ligand exchange between Cu(II) complex with 2-(2-thiazolyazo)-5-dimethylaminophenol and ethylenediaminetetraacetic acid (EDTA) is the basis of a spectrophotometric kinetic method for copper. The substitution of Cu(II) by Ga(III) in the copper–EDTA complex is the basis for a spectrophotometric kinetic method for Ga(III). The exchange between Th–DCTA (diaminohexanetetraacetic acid) complex and the attacking ligand arsenazo(III) can be used for the kinetic spectrophotometric determination of thorium.

The kinetic spectrophotometric determination of chloride using FI mixing and fixed-time approach is based on the following scheme of reactions, Equation (23) and (24):

$$2Cl^- + Hg(SCN)_2 \Longleftrightarrow HgCl_2 + 2SCN^- \quad (23)$$

$$SCN^- + Fe^{3+} \Longleftrightarrow Fe(SCN)^{2+} \quad (24)$$

The displacement of fluoride from its aluminum complexes by EDTA, citrate and α-hydroxyacids is the basis for their potentiometric kinetic determination using fluoride ISE.

3.1.2 Complex formation Reactions

This type of reaction is mainly used for the determination of a single metal ion or an organic substance acting as a ligand. The complexation of iron(III) with thiocyanate is the basis of a spectrophotometric kinetic method for Fe(III). Aluminum can be determined by an initial rate fluorimetric method based on its chelation with 2-hydroxy-1-naphthaldehyde *p*-methoxybenzoylhydrazone. *O*-Cresolphthalein complexone is used as the complexing agent for the spectrophotometric determination of calcium using the SF technique. The complexation of magnesium by calmagite in alkaline medium and in the presence of bis(aminoethyl)glycolether-*N*,*N*,*N*′,*N*′-tetraacetic acid (EGTA) to mask calcium is the basis of a spectrophotometric kinetic method for magnesium.

A selective kinetic spectrophotometric method for zinc is based on its complexation with zincon which follows the differential demasking of the cyanide complexes with cyclohexanone, Equation (25) and (26):

$$[Zn(CN)_4]^{n-} + 4C_6H_{10}O + 4H_2O \longrightarrow Zn^{2+} + 4C_6H_{10}(OH)CN + 4OH^- \quad (25)$$

$$Zn^{2+} + \text{zincon} \Longleftrightarrow \text{blue complex} \quad (26)$$

The formation of molecular complexes has been used in organic kinetic analysis. The reaction of albumin with picrates monitored with a picrate ISE has been

proposed for the determination of albumin in serum. The formation of the characteristic yellow–orange complex of creatinine with alkaline picrate has been the basis of its spectrophotometric or potentiometric (using a picrate ISE) kinetic determinations.

Of special interest are the immunochemical reactions of antigen and haptens with their antibodies. Several drugs of abuse are determined using the fluorescence polarization technique. The specific precipitation of lipoprotein by heparin, calcium ions, EDTA and lipase is the basis of a turbidimetric kinetic method.

3.2 Redox Reactions

Redox reactions have been mainly used for the determination of anionic rather than cationic species in inorganic analysis.

The reduction of iodate to iodine by arsenite in strongly acidic medium is used in an initial-rate spectrophotometric SF method for arsenite. Iodide can be oxidized by perbromate to triodide complex, I_3^-, the spectrophotometric (353 nm) monitoring of which is the basis for the kinetic determination of perbromate (0.3–3 μg). The competitive equilibria of oxidation and complexation between the benzyl 2-pyridyl ketone 2-pyridylhydrazone, bromate and copper(II), nickel(II) and palladium(II) cations is the basis for the spectrophotometric kinetic method (initial rate approach) for these cations. The reduction of Mo(VI) by hydrazine in acidic medium can be used for the kinetic spectrophotometric determination of hydrazine.

The kinetic determination of iodine (0.6–7 ng mL^{-1}) is based on its reaction with acetone in alkaline medium to form iodoform and iodide which is monitored with an iodide ISE (initial rate approach) Equation (27):

$$(CH_3)_2CO + 3I_2 + 4OH^- \longrightarrow CHI_3 + CH_3COO^- + 3I^- + 3H_2O \qquad (27)$$

The oxidation of 4,8-diamino-1,5-dihydroxyanthraquinone-2,6-disulfonate in alkaline medium by manganese in the form of hydrated MnO_2 is the basis for a fluorimetric kinetic method for Mn.

The well-known Karl Fischer reaction for water is the basis for its kinetic SF spectrophotometric determination (1–10 mg mL^{-1}) using an acetate pyridine-free reagent, Equation (28):

$$CH_3SO_3I_2^- + H_2O \longrightarrow CH_3SO_4^- + 2I^- + 2H^+ \qquad (28)$$

Redox reactions are of special interest in organic analysis and rely on the oxidation of organic compounds by a strong oxidant such as permanganate, cerium(IV), iron(III), periodate, dichromate, hexacyanoferrate(III), peroxydisulfate, or hydrogen peroxide.

Periodate is a common oxidant for organic hydroxy compounds including phenols, chlorophenols, hydroxyacids (e.g. tartaric acid) and vicinal glycols (e.g. glycerol) (Malaprade reaction), Equation (29):

$$A + IO_4^- \Longleftrightarrow A \cdot IO_4^- \longrightarrow \text{products} \qquad (29)$$

where $A \cdot IO_4^-$ is an intermediate (periodate ester). Fixed-time (absorbance measurements) and variable-time (perchlorate or home-made periodate-selective electrode) methods can be used for the determination of these species and related substances such as carbohydrates (e.g. glucose).

Peroxydisulfate oxidation of organic carbon is the basis for an automated determination of organic carbon in water samples.

One interesting redox reaction is the reversible interconversion of ferriin/ferroin complexes. The 1,10-phenanthroline/iron(III) complex (ferriin) has been used to oxidize species of clinical (uric acid) and pharmaceutical interest such as analgesics (acetaminophen) and catecholamines, the reaction being monitored by measuring the initial rate change of the absorbance of the ferroin at 510 nm. The ligand 2,4,6-tris-(2-pyridyl)-*s*-triazine (TPTZ) has also been used.

The oxidation of various organic substances (carbamazepine, choline, acetylcholine) with Ce(IV) in acidic medium yields fluorecsent Ce(III) species used for their kinetic fluorimetric determination. Carbimazole is oxidized to a colored product using dichromate or molybdate at 90 °C.

The oxidation of various organic analytes (alcohols and carbohydrates) with dichromate in acidic medium can be monitored with a home-made dichromate ISE and used for their kinetic determination.

The formation of colored unstable free radicals yielded during the oxidation of phenothiazines (chlorpromazine, methotrimeprazine, thioridazine, etc.) with Fe(III) in acidic medium has been used for their spectrophotometric kinetic determination.

The Mn(II)-catalyzed oxidation of oxalate with permanganate has been used for a fast kinetic spectrophotometric determination of oxalate.

Bromosuccinimide oxidizes several organic compounds such as vitamins (pyridoxine, thiamine, ascorbic acid), being reduced to succinimide with the liberation of bromide which can be monitored with a bromide ISE.

3.3 Coupled Reactions

The most typical example of this type of reaction is the so-called Griess reaction, originally developed for the kinetic determination of nitrite. Nitrite in a weakly acidic solution reacts with an amine (usually

sulfanilic acid) to form the corresponding diazonium salt, which then couples with a naphthylamine derivative or naphthol. This reaction can be used for the kinetic determination of nitrate after reduction in a column (copperized cadmium), as well as for measuring other species such as sulfonamides (the Bratton–Marshall reaction), bromhexine, benzodiazepines (e.g. nitrazepam) and *N*-methylcarbamate pesticides, hydrolysis of which yields the corresponding benzophenones (which can be diazotized) and naphthols (useful for the coupling reaction), respectively. Nitroprusside liberates nitrite in alkaline medium and can be determined kinetically using the Griess reaction.

The well-known Berthelot reaction of ammonia is the basis for various kinetic methods for ammonia–nitrogen. Ammonia reacts with hypochlorite to form chloramine which then is coupled with phenol in two steps to form indophenol blue, Equations (30–32):

$$NH_3 + OCl^- \longrightarrow NH_2Cl + OH^- \quad (30)$$

$$2OCl^- + NH_2Cl + C_6H_5O^- \longrightarrow OC_6H_4NCl + 2Cl^- + OH^- + H_2O \quad (31)$$

$$OH^- + OC_6H_4NCl + C_6H_5O^- \longrightarrow OC_6H_4NC_6H_4O^- + H_2O + Cl^- \quad (32)$$

Aminoglycoside antibiotics (amicacin, kanamicin, tobramycin), through their primary amine group, participate in a cyclization reaction with *o*-phthalaldialdehyde and a thiol to form a 1-alkylthio-2-alkylisoindole fluorescent derivative which can be used for their kinetic determination.

Oxidative coupling reactions of *p*-phenylenediamines (PPD) with amines and phenols are widely used. PPD is oxidized to its quinone diimine (QDI) by hexacyanoferrates(III) or a similar oxidant in a weakly basic medium. QDI reacts with the amine or phenol compound to give leucoindamines (leucoindophenols), which are rapidly oxidized to colored indamines (indophenols) with the aid of a QDI molecule.

The reduced form of ascorbic acid (dehydroascorbic acid) obtained using Hg(II) reacts with *o*-phenylenediamine to form fluorescent quinoxaline. The oxidative condensation of *para*- and *meta*-substituted phenols with 1-nitroso-2-naphthol using Ce(IV) or Pb(IV) can be used for the kinetic spectrophotometric determination of phenols.

The so-called bromination reactions use bromine generated in situ from BrO_3^-/Br^- couple in an acidic medium. At low analyte concentrations, the rate of bromination and bromine generation are virtually the same, so methyl orange in the reaction medium will only be decolorized after the bromination process has been completed. The decolorization time will be proportional to the analyte (e.g. acetaminophen) concentration. Bromide can be determined in addition to phenol compounds, which are the typical substrates.

The bromination of the yellow indicator phenol red (PR) to bromothymol blue (BTB) at pH 4.6 using bromine produced by the oxidation of bromide with chloramine-T is the basis for a kinetic determination of bromide using FI mixing and the fixed-time approach, Equations (33) and (34):

$$2Br^- + H_3C{-}C_6H_4SO_2NCl^- + 2H^+ \longrightarrow Br_2 + H_3C{-}C_6H_4SO_2NH_2 + Cl^- \quad (33)$$

$$4Br_2 + PR \Longleftrightarrow BTB + 4H^+ + 4Br^- \quad (34)$$

3.4 Addition Reactions

Formation of addition compounds from species containing carbonyl groups has been exploited for the determination of organic compounds reacting with hydrogen sulfite ion in the presence of acetone, methanol or acetic acid. The addition reaction of sulfite with rosaniline at pH 11.8 has also been used for the kinetic spectrophotometric determination of sulfite. The addition reaction of hydrogen cyanide to carbonyl group (e.g. formaldehyde) monitored with a cyanide ISE has been used for its kinetic determination. Aromatic aldehydes have been determinated spectrophotometrically using their condensation reaction with barbituric acid. Primary and secondary amines (e.g. amphetamine, ephedrine) react with 1,2-naphthoquinone-4-sulfonate to form a colored product which is the basis for their kinetic determination. The reaction of amino acids with ninhydrin (a dihydroxyindanedione) at 80 °C is the basis for their kinetic photometric method. Tryptophan reacts with formaldehyde in alkaline solution to form a highly fluorescent product.

Urea reacts with the unstable diacetyl (produced in situ by the acidic hydrolysis of diacetyl monoxime) to form a yellow diazine derivative.

3.5 Aromatic Substitution Reactions

Several reagents capable to undergo aromatic substitution reactions with various substances owing reactive functional groups have been proposed for the kinetic determination of these substances. A characteristic example is the reaction of 1-fluoro-2,4-dinitrobenzene (FDNB) with amines, amino acids, phenols, thiols, hydrazines, and hydrazides. The reaction, through the formation of an intermediate complex (Meisenheimer complex)

Table 2 Selected noncatalytic determinations of inorganic single species

Analyte	Chemical system	Concentration range or LOD ($\mu g\,mL^{-1}$)	Comments
Aluminum	Complex formation with fluoride (pH 3)	5–50 μM 20–200 μM	CF/SF with fluoride ISE detector (slope approach). Application in tea leaves
Aluminum	Complex formation with chrome azurol S, eriochrome cyanin R, pyrocathechol	0.060–30 μM	Spectrophotometric FIA. Estimation of kinetically labile Al in soils
Ammonia nitrogen	Berthelot reaction (phenol–hypochloride)	20–250	FI/SF system, multipoint reaction rate approach
Boric acid	Pseudotitration with mannitol in the presence of BTB indicator	2.5×10^{-4}–5×10^{-2} M	FIA spectrophotometric gradient system. Measurement of width of absorbance peaks (Δt vs $\log C$). Application in pharmaceutical formulations
Bromide	Reaction with chloramine-T to produce bromine and bromination of PR to bromophenol	1–10	FIA spectrophotometric system, fixed time approach. Application in waters, serum and pharmaceutical formulations of bromide salts of drugs and dissolution studies
Cerium(IV)	Oxidation of 4,8-diamino-1,5-dihydroxyanthraquinone-2,6-disulfonate	0.02–0.37	Fluorometric monitoring, initial-rate approach
Copper	Complexation with 5,5-dimethyl-1,3-cyclohexanedione bis(4-phenyl-3-thiosemicarbazone) in acidic medium	0.8–8	Spectrophotometric monitoring, Fixed-time and initial-rate approaches
Copper(II) or Zinc	Incorporation in coproporphyrin-I	$0–1 \times 10^{-5}$ M	Monitoring the decrease in fluorescence of free base porphyrin. Initial rate or fixed-time approach
Germanate	Formation of molybdenum germanate blue		Spectrophotometric monitoring
Hydrazine or sodium azide	Liberation of fluoride during the reaction with FDNB	$1–10 \times 10^{-4}$ M	Initial rate approach using fluoride ISE
Hypochlorite	CL reaction with luminol	0.0015–10	SF CL spectrometer. Formation rate, decay rate, peak height and peak area were used to construct calibration curves. Application in waters
Iodide	Reduction of iodate with hydrazine	region of 2	Monitoring with iodide ISE. Time required to generate sufficient iodide to cause the iodate–iodide reaction to become predominant is related to iodide concentration
Iron(III) and Thallium(III)	Oxidation transformation of 1,4-diamino-2,3-dihydroxy-anthraquinone	0.05–0.6 for Fe 0.05–0.4 for Th	Fluorometric monitoring, initial rate approach
Manganese(II)	Complexation with terephthal-monohydroxamic acid (pH 10.3)	1.25–7.25	Spectrophotometric monitoring, initial-rate approach. Application in steels
Mercury(II)	Liberation of cyanide from the reaction with 1,10-phenathroline and ferrocyanide	0.010–0.2 μM	Monitoring with Ag-coated piezoelectric quartz crystal for 4 min
Nickel	Compexation with xylenol orange in the presence of hexadecyl-trimethylammonium bromide	0–0.56	Spectrophotometric monitoring using a flow system. Application in nickel ores
Niobium	Complexation with 4-(2-pyridylazo)resorcinol in the presence of tartrate to mask tantalum(V)	0.5–20 μM	Spectrophotometric monitoring. Fixed-time approach
Nitrate	Liberation of nitrite using on-line reduction with copperized cadmium and subsequent diazotization and coupling with NEDD	0.025–3	Spectrophotometric SF monitoring, initial-rate and fixed-time approaches. Application in waters

Table 2 (*continued*)

Analyte	Chemical system	Concentration range or LOD ($\mu g\,mL^{-1}$)	Comments
Nitrate	Liberation of nitrite after reduction with cadmium, diazotization with sulfanilamide and coupling to NEDD	2–250 μM	Spectrophotometric monitoring, fixed-time approach. Application to serum and urine
Nitroprusside	Liberation of nitrite in alkaline medium, diazotization with sulfadiazine and coupling reaction with *N*-(1-naphthyl)-ethylenediamine	0.1–100	Spectrophotometric monitoring initial rate approach. Application in pharmaceutical formulations
Phosphorus	Formation of molybdophosporic acid and reduction to phosphomolybdenum blue by ascorbic acid	(i) 20–100	(i) Spectrophotometric SF, reaction-rate approach (2–6 s). Application in feed samples
		(ii) 5–30	(ii) FI/SF system, multipoint reaction rate approach
Selenite	Reduction by ascorbic acid to elemental selenium	10^{-5} M level	Turbidimetric monitoring (460 nm), fixed-time procedure
Sulfide	Reduction of resazurin in the presence of Cu(II) and ethylenediamine	0.05–6	Spectrophotometric monitoring, fixed-time and slope approaches
Sulfite	Reduction of methyl green	0.05–25	Monitoring of decrease in absorbance, fixed-time approach
Sulfite	Reduction of: Fe(III)-1,10-phenanthroline Fe(III)-2,2′-bipyridyl	0.2–5	Spectrophotometric monitoring
Sulfite	Addition reaction with rosaniline (pH 11.8)	0.015	Spectrophotometric monitoring, slope approach. Application in beverages, biscuits and steamed buns
Sulfite	Oxidation with iodate producing iodide in acidic medium	5×10^{-5}–5×10^{-3} M	Reciprocal-time approach using iodide ISE
Technetium	Color formation with 1,3,5-triphenyl-Δ^2-pyrazoline	0.01–12	Initial-rate and fixed-time approaches
Thiocyanate	Inhibition of the ferroin – periodate reaction in acidic medium	20–200 $ng\,mL^{-1}$	Monitoring of decrease in absorbance, initial rate approach. Application in human serum and saliva
Vanadium(V)	Oxidation of 1-amino-4-hydroxyanthraquinone	100–530 $ng\,mL^{-1}$	Fluorimetric monitoring, initial rate method. Application in crude petroleum
Zinc	Complexation with zincon in the presence of cyanide to mask interfering metal ions and cyclohexanone to dissociate the zinc-cyanide complex	1–10	FIA spectrophotometric system. Fixed-time approach. Application in waters, alloys and insulin formulations

LOD, limit of detection; CF/SF, continuous flow/stopped flow; NEDD, *N*-(1-naphthyl)ethylenediamine dihydrochloride.

leads to the formation of a dinitrobenzene (DNB)-derivative (capable of spectrophotometric monitoring) and the release of fluoride ion (capable of potentiometric monitoring with a fluoride ISE) Equation (35):

$$\begin{aligned} RNH_2 + (NO_2)_2C_6H_3F &\Longleftrightarrow (NO_2)_2C_6H_3(F)NH_2R \\ &\longrightarrow (NO_2)_2C_6H_3NHR \\ &\quad + H^+ + F^- \end{aligned} \tag{35}$$

These rather slow reactions can be accelerated by cationic surfactants using micellar catalysis. Several spectrophotometric and potentiometric methods using manual or FI mixing have been proposed for a great number of substances of pharmaceutical interest.

The nucleophilic substitution reaction of trinitrobenzenesulfonate (TNBS) with amino acids and carbohydrates in an alkaline medium monitored with a TNBS home-made ISE has been used for the kinetic determination of the analytes, Equation (36):

$$\begin{aligned} RNH_2 + (NO_2)_3C_6H_2{-}SO_3^- &\longrightarrow (NO_2)_3C_6H_2{-}NHR \\ &\quad + SO_3^{2-} + H^+ \end{aligned} \tag{36}$$

3.6 Hydrolysis Reactions

Several hydrolysis reactions have been used for kinetic-based determinations. The alkaline hydrolysis of furazolidone, furaltadone, and methyl parathion can be used for their spectrophotometric kinetic determination. The oxidative (H_2O_2) alkaline hydrolysis of chlopyrifos is the basis for its kinetic determination. The alkaline hydrolysis of *p*-chloranil yields chloranilate which can be monitored with a chloranilate home-made ISE.

The acid degradation with heating of tetracycline and oxytetracycline to the anhydro derivatives is the basis of their spectrophotometric determination.

3.7 Chemiluminescence Reactions

While the main field of application of chemiluminescence (CL) reactions is catalytic processes (determination of inorganic catalysts and various inhibitors) and senzitization processes (by energy transfer and stabilization), some noncatalytic reactions are also of great interest on account of the high sensitivity they provide. Some characteristic examples of such reactions are that of hypochlorite with luminol for the determination of hypochlorite, the reaction of acetaminophen with Ce(IV) in acidic medium, and the reaction of ethanol with MnO_4^- in very acidic solutions.

4 ANALYTES DETERMINED[5,9–11]

4.1 Determination of Inorganic Species

Complex formation and redox reactions are mainly used for the determination of metals and nonmetals. Table 2 presents selected kinetic methods for inorganic species. The majority of these methods are based on photometric detection and the concentration ranges typically are in the micrograms per milliliter region.

4.2 Determination of Organic Species

Kinetic methods of analysis based on noncatalyzed reactions are very attractive in organic analysis, since they generally lack a catalytic activity. All types of reactions have been used in kinetic organic analysis and the majority of the reactions are monitored spectrophotometrically and fluorimetrically. Table 3 shows selected examples of kinetic methods employed in organic analysis.

5 APPLICATION AREAS

The increased automation of kinetic methods, especially in organic analysis, using a variety of commercial or home-made analyzers of various types (FI, SF, etc.) has resulted in a tremendous increase in the use of noncatalytic kinetic methods. The advantages of short analysis time, high precision and the absence of serious interferences make the application of uncatalyzed kinetic methods very attractive for routine analysis of real samples in a variety of areas. Clinical, environmental, food and pharmaceutical analysis are the areas where kinetic methods are applied with success and are discussed below.

5.1 Clinical Analysis

The following inorganic and organic species can be determined in serum and/or urine using kinetic methods based on noncatalytic reactions:

- **Serum:** Aluminum, bromide, calcium, magnesium, nitrate, phosphate, thiocyanate.
  Acetaminophen, ascorbic acid, carbamazepine, malonaldehyde. Albumin, creatinine, lipoprotein, total serum protein, urea, uric acid, hemoglobin, methemoglobin, reduced glutathione.
- **Urine:** Nitrate, phosphate.
  Amphetamines, ascorbic acid, morphine, sulfonamides. Catecholamines, creatinine, uric acid.

Some of the methods can be applied directly on the biological sample (urea, uric acid and phosphate) but others required treatment (protein precipitation, liquid–liquid extraction, solid-phase extraction (Sep-Pack cartridges) etc.). The detectability and sensitivity of the kinetic methods are suitable so that a rather low volume of sample is required (20–500 μL of serum). Most kinetic methods can be performed using automated clinical analyzers (centrifugal, batch, and flow analyzers).

5.2 Environmental Analysis

The application of kinetic methods in this area is extensive. The sample matrix (natural-, waste- and seawaters) is simple allowing direct determinations without any treatment. Water and air samples can very easily be analyzed using automated apparatus.

The following species, most of them being inorganic, can be determined in various environmental samples using noncatalytic kinetic methods:

- Air: carbon dioxide, manganese, nitrogen oxides.
- Natural waters: arsenite, hydrazine, hypochlorite, iodine, magnesium, manganese, nitrates, nitrite,

Table 3 Selected noncatalytic determinations of organic single species

Analyte	Chemical system	Concentration range or LOD ($\mu g\,mL^{-1}$)	Comments
Acetaminophen	Reduction of Fe(III) in the presence of TPTZ	50–500	Spectrophotometric monitoring (593 nm), FI mixing, fixed-time approach. Application in drug formulations and dissolution studies. An alternative method uses SF mixing and initial rate approach ($20–200\,\mu g\,mL^{-1}$). In the presence of chlorpromazine the reaction is catalyzed allowing determination in the range $0.5–6\,\mu g\,mL^{-1}$ in serum after extraction
Acetaminophen	Reduction of Ce(IV) in acidic medium	1–10	Continuous flow mixing with chemiluminometric detector, fixed-time approach. Application in drug formulations
Acetaminophen (paracetamol)	Reaction with hexacyanoferrate(III), pH 8.5	0.5–15	FIA/SF fluorimetric system. Reaction rate approach (5.8 s). Application in pharmaceutical formulations
Albumin	Binding with picrate at pH 5.0	$10–70\,g\,L^{-1}$	Air-segmented continuous flow system with a picrate ISE flow detector. Fixed-time approach. Application in serum
Albumin	Reaction with bromcresol green	$0–68\,g\,L^{-1}$	Spectrophotometric monitoring, SF mixing, fixed-time (10 s) approach. Application in serum
Aldehydes (aromatic)	Condensation reaction with barbituric acid	$1 \times 10^{-6} - 5 \times 10^{-4}$ M	Spectrophotometric monitoring
Amines (primary and secondary)	Color formation by reacting with 1,2-naphthoquinone-4-sulfonate in the presence of Triton X-100, pH 10.5		Spectrophotometric monitoring, reaction rate (45–180 s) approach. Application in pharmaceutical formulations (amphetamine, ephedrine)
Amino acids	Reaction with ninhydrin at 80 °C	$(1–5) \times 10^{-5}$ M	Photometric monitoring at 570 nm. Absorbance versus time data from the kinetic region of reaction (1–3 half-lives) are fitted to a first -order model to predict total absorbance change at equilibrium
Amino acids and amines	Reaction with FDNB at pH 9 yielding fluoride ions	$1 \times 10^{-4} - 5 \times 10^{3}$ M	Monitoring with fluoride ISE. Initial-rate and fixed time approaches. Application in drug formulations
Amino acids, carbohydrates	Reaction with TNBS at pH 12	$3 \times 10^{-4} - 3 \times 10^{-3}$ M	Monitoring with TNBS ISE. Initial-rate or variable-time approaches
Ascorbic acid	Reaction with 2,6-dichlorophenol indophenol	$2 \times 10^{-7} - 2 \times 10^{-5}$ M	SF mixing, spectrophotometric monitoring (10 s)
Ascorbic acid	Rapid oxidation by mercury(II) to dehydroascorbic acid, which then reacts with *o*-phenylenediamine to form fluorescent quinoxaline	0.02–10	Spectrofluorimeter system with automated injector. Reaction rate measurement (20 s) after a delay time of 5 s. Application in drug formulations and juices
Ascorbic acid	Photochemical reaction with methylene blue	20–200	Various flow manifolds with irradiation of the reaction coil or the flow cell. Reaction rate and fixed time approaches. Application in drug formulations and fruit juices

(*continued overleaf*)

Table 3 (*continued*)

Analyte	Chemical system	Concentration range or LOD ($\mu g\,mL^{-1}$)	Comments
Ascorbic acid	Reduction of toluidine blue	3–35	Spectrophotometric monitoring of decrease in absorbance, slope and fixed time approaches. Application in fruits and vegetables
Aspartame	Reaction with FDNB in the presence of CTAB micelles to yield colored DNB derivative	$(0.1–6) \times 10^{-4}$ M	Spectrophotometric monitoring (342 nm), FI/SF mixing, slope method. Application in beverages
Bromazepam	Complexation reaction with Fe(II) in acidic medium	$5 \times 10^{-4}–1.5 \times 10^{-3}$ M	Sequential injection technique, spectrophotometric monitoring (585 nm), fixed-time (100 s) approach. Application in drug formulations
Bromhexine hydrochloride	Coupling reaction of diazotized bromhexine derivative and NEDD	1.5–65	SF system, spectrophotometric monitoring at 495 nm. Initial reaction rate approach. Application to drug formulations without interference from antibiotics (penicillins and cephalosporins)
Carbamazepine	Oxidation with Ce(IV) in acidic medium	0.04–140	SF system with fluorimetric monitoring, initial rate approach. Application in serum after extraction
Carbimazole	Oxidation by dichromate or molybdate in acidic medium at 90 °C		Spectrophotometric measurement (585 or 650 nm), fixed-time (25 or 12 min) approach. Application in drug formulations
p-Chloranil	Alkaline hydrolysis to monochloranilate in a fast step and to chloranilate in a slow step	5–500	A chloranilate ISE monitors both anions and the potential change at the end of the first fast step is proportional to log *C* of *p*-chloranil. Application in fungicide preparation
Chlorpyrifos	Oxidative (H_2O_2) alkaline hydrolysis	$6.6 \times 10^{-6}–2 \times 10^{-2}$ M	FIA/SF system, spectrophotometric monitoring (328 nm), initial rate approach. Application in pesticide formulation
Choline and acetylcholine	Oxidation with Ce(IV) in acidic medium to yield fluorescent Ce(III)	$1.7 \times 10^{-5}–1 \times 10^{-3}$ M	Fluorimetric monitoring, reaction rate approach
Citric acid	Reaction with perbromate induced by Fe(II) at pH 4.75	96–960 μg	Monitoring with perbromate ISE. Fixed-time approach (6 min). Interference by tartaric and lactic acids
Corticosteroids	Reaction with tetrazolium blue in alkaline medium to form red formazan	mg dL^{-1} levels	Spectrophotometric monitoring (525 nm), SF mixing, slope approach after a delay time. Application in skin preparations
Creatinine	Jaffe reaction (alkaline picrate)	0.5–4 g L^{-1}	Monitoring with a picrate ISE. Fixed time (30 and 270 s). Application in serum and urine. Method free from optical interferences and bilirubin interference
Creatinine	Jaffe's reaction (picric acid in alkaline solution) at 37 °C	0.5–2 g L^{-1}	FIA, spectrophotometric monitoring, fixed-time approach. Application in urine. An alternative method uses FI/SF slope approach
Dehydroascorbic acid	Formation of mixture of methyl ketals by reacting with aqueous methanol-containing phosphate or citrate buffers. Ascorbic acid is masked using transition metal complexing agents	0–350 μM	Spectrophotometric monitoring at 346 nm. Methyl ketals were analyzed with fast atom bombardment mass spectrometry

Table 3 (*continued*)

Analyte	Chemical system	Concentration range or LOD ($\mu g\,mL^{-1}$)	Comments
Diaquat	Charge-transfer complexation with cysteine	0.5–28	Spectrophotometric monitoring (495 nm), initial rate approach (60 s). Application in herbicides, waters, soils and potatoes
2,4-Dinitrophenyl-hydrazine	Monitoring of the decomposition of the unstable green product formed by reacting with piperidine in dimethyl sulfoxide	0–120	Spectrophotometric monitoring (640 nm)
Drugs of abuse (amphetamines, cocaine, cannabinoids)	Immunochemical reaction	20–300 $ng\,mL^{-1}$ (Amphetamine)	SF fluorescence polarization system, measuring variation of polarized fluorescence. Application in urine
EDTA, citrate	Displacement of fluoride from its aluminum complexes by EDTA, citrate and α-hydroxyacids	0.2–1.5 μmol EDTA, 0.1–1 μmol citrate	Monitoring of fluoride liberation with fluoride ISE. Initial rate ($\Delta E/\Delta t$) approach
Ethanol	Reaction with MnO_4^- in very acidic solutions	LOD 0.3% (v/v)	CL monitoring. Fitting of data with second order polynomial. Application in gin
Ethanol, other alcohols and carbohydrates	Reaction with dichromate in acidic medium (4.5 M H_2SO_4)	0.03–1.2 M	Monitoring with a dichromate ISE. Initial slope ($\Delta E/\Delta t$) approach. Application in beverages
Formaldehyde and hexamethylene-tetramine	Addition reaction of hydrogen cyanide to carbonyl group at pH 7.8. Hexamethylene-tetramine is determined after acid hydrolysis	60–300	Monitoring of rate of CN^- consumption with a cyanide ISE. Variable-time approach. Application in drug formulations
Furazolidone, furaltadone	Alkaline hydrolysis	1–20	Spectrophotometric monitoring, tangents approach. Application in pharmaceutical and feed products
Glucose	Reaction with periodate at pH 4.5	0.02–0.15 M	Monitoring with a perchlorate/periodate ISE. Variable time approach. Application to other carbohydrates
Glutathione (reduced)	Reaction of reduced glutathione with Cu(II) to yield Cu(I) which in turn reacts with neocuproine to form a colored complex	1.6–160 μM	Continuous addition of reagent (Cu(II)) technique. Spectrophotometric monitoring (455 nm). Application in blood
Glycerol	Reaction with periodate at pH 4.5	2.8×10^{-4}–0.12 M	Monitoring with periodate ISE. Slope or variable-time approaches. Application in soaps
Hb	Peroxidation of chlorpromazine by Hb	3–200 $mg\,L^{-1}$	Spectrophotometric monitoring (528 nm), reaction rate approach (3 min). Application in plasma and urine
α-Hydroxyacids	Reaction with periodate accelerated by Fe(II) or hexacyanoferrate(II)		Monitoring with periodate ISE. Fixed-time (90 s) approach
Isoniazid	Formation of hydrazone with 2-hydroxy-1-naphthaldehyde in acidic medium and consequent formation of a strongly fluorescent complex with scandium in weakly acidic medium	0–5	Fluorimetric monitoring. Fixed-time approach (1 min)

(*continued overleaf*)

Table 3 (*continued*)

Analyte	Chemical system	Concentration range or LOD ($\mu g\,mL^{-1}$)	Comments
Maleimides	Reaction with hydroquinone and H_2O_2 in the presence of Cu(II)	0.5–15	Spectrophotometric monitoring, reaction rate approach (3 min)
Malonaldehyde	Reaction with thiobarbituric acid at 65 °C	1.1–50 $ng\,mL^{-1}$	Fluorimetric monitoring, reaction rate approach (400–500 s). Application in human serum
Malonaldehyde	Hantzsch reaction (with methylamine in the presence of propan-2-ol), 75 °C	0.5–2.8	Monitoring of fluorescence, reaction rate approach (1250–1450 s). Application in olive oil
mHb, Hb	Reaction with cyanide to produce CNmHb (monitoring of disappearance of mHb at 630 nm). To determine Hb the whole blood reacts with ferricyanide to produce mHb (monitoring of increase in absorbance at 630 nm)	5.6–56 $mmol\,L^{-1}$	SF (measurement time 250 ms) or centrifugal (measurement time 30 s) mixing. Absorbance data are fitted to first-order model by nonlinear regression method to calculate ΔA_∞ values
Methotrimeprazine, thioridazine	Reaction with Fe(III) in acidic solution at 50 °C	0.8–60 1.1–60	SF/diode-array system, reaction rate approach (5 s). Application in pharmaceutical formulations
Methyl parathion	Alkaline hydrolysis at 55 °C	2–30	Spectrophotometric monitoring at 400 nm. Initial rate and fixed time approaches. Application in formulations and surface waters
Morphine	Reaction with $Fe(CN)_6^{3-}$ at pH 10	15–925 $ng\,mL^{-1}$	Continuous addition of reagent method, fluorimetric monitoring. Application in urine after ion-exchange separation
Morphine	Reaction with FDNB at pH 9 at 35 °C to liberate fluoride ions	20–200 μM	Monitoring with fluoride ISE. Initial rate approach. Application in pharmaceutical formulations
Nitrazepam	Formation of azo dye with 1-naphthol after the acidic hydrolysis of the drug to 2-amino-7-nitrobenzophenone and diazotization	0.58–2.9	Continuous addition of reagent technique (addition of the coupling reagent at a rate of 35 $mL\,min^{-1}$ with stirring). Spectrophotometric monitoring at 600 nm. Application in drug formulations. Similar method for oxazepam
Nortriptylin	Reaction with 4-chloro-7-nitrobenzofurazan, pH 8.2 at 50 °C	0.12–60	SF system, spectrophotometric (470 nm) and fluorimetric monitoring. Reaction rate approach (30 s). Application in drug formulations
Organic peroxides and lipohydroperoxides	Mn(II)-catalyzed oxidation of 2-hydroxynaphthaldehyde thiosemicarbazone	0.08–1.6 μM	Fluorimetric monitoring, initial rate approach. Application in commercial oils
Oxalate	Reduction of permanganate catalysed by Mn(II) in acidic medium	0–20	Spectrophotometric monitoring of the first fast step of the reaction at 525 nm. SF mixing, initial rate approach
Phenolic (acetaminophen, isoxsuprine) and hydrazino (isoniazid) drugs	Reaction with FDNB in weakly alkaline medium to liberate fluoride catalyzed by CTAB micelles	$(1–50) \times 10^{-4}$ M	Automated FI system with a fluoride ISE in wall-jet configuration. Fixed-time approach (measurement of ΔE). Application in drug formulations
Phenols (*para* and *meta* substituted phenolic drugs)	Oxidative condensation with 1-nitroso-2-naphthol using Ce(IV) or Pb(IV) as oxidant	$(1–8) \times 10^{-4}$ M	Spectrophotometric monitoring (510, 540 nm), FI mixing, fixed-time approach. Application in drug formulations (acetaminophen, isoxsuprine, amoxicilline, etc.)

Table 3 (*continued*)

Analyte	Chemical system	Concentration range or LOD ($\mu g\,mL^{-1}$)	Comments
Phenols (phenolic drugs)	Reaction with FDNB to yield fluoride ions in the presence of CTAB micelles	6×10^{-6}–7×10^{-4} M	Monitoring with a fluoride ISE, initial slope approach. Application in drug formulations (acetaminophen). An alternative method uses FI mixing and fixed-time approach
Phenothiazines	Oxidation by Fe(III) in very strong acidic medium to form unstable colored free radicals	10–250	Spectrophotometric monitoring (500–580 nm), FI mixing, fixed-time approach. Application in drug formulations and dissolution studies
1-PCC	Reaction with *p*-nitrobenzaldehyde and *o*-DNB. Starting with NaOH and quenching with ethanol after 45 min	0.1–0.7 μg	Spectrophotometric measurement (555 nm), fixed-time approach. Application in illicit samples
Salicylates, salicylamide, methyl salicylate	Trinder reaction (Fe(III) in weak acidic medium) yielding colored complex	25–1000	Spectrophotometric monitoring (540 nm), FI mixing, fixed-time approach. Application in drug formulations and dissolution studies
Sulfonamides	Azo dye formation between 1-naphthol and diazotized sulfonamide, pH 4.15	$(3–30) \times 10^{-6}$ M	Continuous addition of reagent (nitrite) technique. Spectrophotometric monitoring (470 nm), reaction rate approach. Application in drug formulations
Sulfonamides	Griess reaction (nitrosation and coupling with NEDD)	$(0.5–5) \times 10^{-5}$ M	SF mixing, photometric monitoring, variable time approach. Application in urine
Sulfonamides	Bratton–Marshall reaction (nitrosation and coupling with NEDD)	2–20	Spectrophotometric monitoring (545 nm), FI mixing, fixed-time approach. For the range 5×10^{-4}–5×10^{-3} M a FI pseudotitration approach is used. Application in serum, urine, feeds, drug formulations and dissolution studies
Tartaric acid	Reaction with periodate	0.4–120 μmol	Monitoring with a periodate ISE, initial rate ($\Delta E/\Delta t$) method. Application in drug formulations and impurities of citric acid
Tetracycline and oxytetracycline	Degradation with strong acids to the anhydro derivatives after a heating time of 30 min	8–40	Measurement of absorbance difference (fixed time approach) in comparison with alkaline solutions. Application in drug formulations
Theophylline	Formation of a 1 : 1 complex between the oxidation product of theophylline with Ce(IV) oxidant	1–250	SF mixing, fluorimetric monitoring, initial rate method (8 s). Application in drug formulations
Thiamine	Oxidation by Hg(II) in basic medium to form a fluorescent thiochrome	2×10^{-8}–1×10^{-4} M	Spectrofluorimeter with fixed-time digital ratemeter, initial rate approach. Application in vitamin and mineral preparations
Thiamine	Oxidation by ferricyanide in basic medium to fluorescent thiochrome	8.3×10^{-9}–7.5×10^{-6} M	Continuous addition of reagent technique. Fluorimetric monitoring, reaction rate approach. In an alternative method continuous flow mixing (fixed time approach) and chemiluminometric detection is used

(*continued overleaf*)

Table 3 (*continued*)

Analyte	Chemical system	Concentration range or LOD ($\mu g\,mL^{-1}$)	Comments
Thiols (thiolic drugs)	Reaction with FDNB in the presence of cationic micelles to yield fluoride ions		Monitoring with a fluoride ISE, fixed time approach. Application for thioglycolic acid in cosmetic formulations
Tryptophan	Reaction with formaldehyde at pH 10.8	$0-100\,nmol\,mL^{-1}$	Fluorimetric monitoring, fixed-time (60 s) approach. Application in foods and foodstuffs after alkaline hydrolysis with $Ba(OH)_2$
Urea	Reaction with biacetyl in acidic medium to yield a colored product in the presence of thiosemicarbazide and iron(III) to enhance and stabilize the color	0.5–15	SF system, spectrophotometric monitoring (530 nm). Initial rate approach. Application in serum
Uric acid	Analyte reduction of $Mn(CN)_5NO^{2-}$ at pH 10	$1-100\,\mu M$	Spectrophotometric monitoring (384 nm), tangent or fixed-time approach
Uric acid	Reaction with 1,1,3-tricyano-2-amino-prop-1-ene and H_2O_2, pH 9.2.	0.08–3	SF mixing, fluorimetric monitoring, Application in serum and urine
Uric acid	Reduction of Fe(III) in the presence of TPTZ		Photometric monitoring (593 nm), fixed-time approach (1 and 3 min). Application in undeproteinized serum
Vicinal glycols	Malaprade reaction (periodate)	0.14–7 mM	Monitoring with periodate ISE, variable-time approach
Vitamins (pyridoxin, thiamine, ascorbic acid, biotin)	Reaction with *N*-bromosuccinimide to yield bromide ions	$\mu g\,mL^{-1}$ levels	Monitoring with bromide ISE. Initial reaction rate approach. Application in drug formulations
Zineb (zinc-containing thiocarbamate-type pesticide and fungicide)	Complexation of zinc ions (produced from the acidic decomposition of zineb) with zincon	0.25–3	Continuous addition of reagent (zincon) technique. Spectrophotometric monitoring (620 nm), initial reaction rate approach. Application in zineb formulations and vine and olive leaves

mHb, methemoglobin; Hb, hemoglobin; PCC, piperidinocyclohexanecarbonitrile; CTAB, cetyltrimethylammonium bromide.

phosphate, silicate; carbaryl, carbofuran, diaquat, nitrilotriacetic acid.

- Sea and river waters: aluminum, bromide, calcium, magnesium, methyl parathion.
- Wastewaters: benzaldehyde, formaldehyde, mercury, nitrite.
- Soils and plants: aluminum (labile) (soils), carbaryl (vegetables), carbofuran (soils), diaquat (soils), zineb (vine and olive leaves).

5.3 Food Analysis

Several inorganic and organic species can be determined in a variety of food samples. Special treatment of the sample is required before the application of the kinetic method. The most frequently determined species are ascorbic acid, iron and phosphate.

The following species can be determined using uncatalyzed kinetic methods in food sample: calcium, iron, magnesium, crude protein, phosphorus, tryptophan, sulfonamides (animal feed), ascorbic acid (juices, green tea, potatoes, red pepper, spinach and strawberry), aluminum (spinach and tea leaves), aspartame (beverages), bromate (bread), butylated hydroxyanisole (vegetable oils), ethanol (gin and beverages), iron (wines), malonaldehyde (olive oil), nitrite (liver oil, cured meat), organic peroxides (oils), sucrose (milk and soft drinks), sulfite (beverages, biscuits, steamed buns), tryptophan (vegetables and fish).

5.4 Pharmaceutical Analysis

The quality control of drugs (assay of content, content uniformity, dissolution studies) requires a great number of determinations and automated kinetic methods are

attractive for this purpose. All kind of pharmaceutical formulations (capsules, injections, ointments, tablets, syrups) have been analyzed for several drugs using kinetic methods without serious interference from the excipients. Potentiometric kinetic methods using ISEs can be successfully applied in colored and cloudy sample solutions. The FIA has found tremendous use in routine pharmaceutical analysis using kinetic methods and has been successfully employed in dissolution studies of solid formulations (tablets and capsules), providing complete dissolution profiles.

The following drugs have been determined in pharmaceutical formulations: acetaminophen, aminoglycoside antibiotics, amoxicilline, amphetamine, ascorbic acid, benzocaine, bismuth, boric acid, bromazepam, bromhexine, bromide salts of drugs, carbimazole, catecholamines, chloride salts of drugs, chlorpromazine, corticosteroids, cyanocobalamin, ephedrine, furazolidone, furaltadone, hexamethylenetetramine, isoniazid, isoxsuprine, methotrimeprazine, morphine, nitrazepam, nitroglycerine, nitroprusside, nortriptylin, oxazepam, perphenazine, phenothiazines, procaine, salicylamide, sulfonamides, tartaric acid, tetracyclines, thiamine, thioridazine, theophylline, zinc.

ABBREVIATIONS AND ACRONYMS

BTB	Bromothymol Blue
CAR	Continuous Addition of Reagents
CF/SF	Continuous Flow/Stopped Flow
CL	Chemiluminescence
CTAB	Cetyltrimethylammonium Bromide

Liquid Chromatography: Introduction

John G. Dorsey
Florida State University, Tallahassee, USA

Liquid chromatography is more than likely *the* most used method of analysis for compounds in solution. Entire industries depend on the separation power of this modern analytical technique; walking through any pharmaceutical company in the world will show a liquid chromatograph on almost every bench! Yet chromatography by its nature can be thought of as a necessary evil. That is, it is a dilution technique which takes some length of time to occur. In other words, we apply a certain concentration of a sample to the top of a column, wait for seconds or minutes, and then try to detect a lower concentration of the components in the mixture! The rationale for this process is the elegant separations possible. If the other analytical techniques were selective enough, there would be no need for chromatographic separations. This is not likely to occur anytime soon, except for the simplest mixtures. It is still easier to detect a lower concentration of a pure component in a solvent stream than to measure it selectively in a complex mixture. Chromatography can also be thought of as a violation of the second law of thermodynamics. Mother Nature favors mixtures and we are asking her to let us perform a separation. The price she extracts is in either concentration or recovery, and we must pay in one currency or the other.

Since its invention in 1906 by Tswett, liquid chromatography has changed dramatically in terms of understanding and controlling the chemistry of the separation process, yet it has also remained virtually unchanged in its form. A translated paragraph from Tswett's first publication in a Russian botany journal is fascinating:

> ''If a petroleum ether solution of chlorophyll is filtered through a column of an adsorbent (I use mainly calcium carbonate which is stamped firmly into a narrow glass tube), then the pigments according to the elution sequence are resolved from top to bottom into various colored zones, since the stronger adsorbed pigments displace the weaker adsorbed ones and force them farther downwards. This separation becomes practically complete if, after the pigment solution has flowed through, one passes a stream of pure solvent through the adsorbent column. Like light rays in the spectrum, so the different components of a pigment mixture are resolved on the calcium carbonate column according to a law and can be estimated on it qualitatively and also quantitatively. Such a preparation I term a chromatogram and the corresponding method, the chromatographic method.''

We have instrumentalized the technique, miniaturized the technique, and have learned to control the chemistry of the mobile and stationary phases, yet in the simplest terms the technique as practiced today has changed very little from that earliest description.

The articles that follow encompass all of the important methods and concepts of this separation technique, and are authored by some of the world's leaders. From stationary phase chemistry to separation mechanisms to electrophoresis, thin-layer chromatography and supercritical fluid chromatography, we have attempted to cover all of the important areas. Entire volumes could be (and have been!) written on each of these subjects. By necessity we have limited the coverage to the basics while maintaining breadth.

Affinity Chromatography is one of the most selective of the separation methods, and can be thought of as ''digital'' chromatography. That is, a column is designed to retain a specific analyte, or very closely related analytes, while everything else in the sample is unretained. The analyte of interest is then ''released'' from the column and quantitated. While simple in description, the design of highly selective columns is very challenging!

The article **Biopolymer Chromatography** shows the power of the technique for the analysis of biological compounds. Biology and chemistry are merging, and the chemical analysis of complex biological systems has opened entire new frontiers to analytical chemists. Separations of polypeptides, proteins, and even cells are possible, but challenging. A protein will interact differently with a stationary phase in its native and denatured form, may denature upon contact with some stationary phases, and gives different retention times and peak shapes depending upon its conformation. In fact, column chromatography has been used to measure denaturation rate constants!

Capillary Electrophoresis is the newest high-resolution separation method, and grew very rapidly through the 1980s and 1990s. However, the sale of instruments has remained virtually flat since the introduction of commercial instrumentation in 1989, while the growth of publications has been almost exponential. Is this just a toy for academicians? It is a very important tool for the bio-tech industry, for DNA sequencing, and other specialized separations, but will likely never be the replacement for liquid chromatography that some originally thought.

The human body is chiral, and because of this both the study of life processes and the design of efficacious pharmaceutical compounds require efficient separations of racemic mixtures. The separation of optical isomers has been a great challenge for separation chemists. Yet that most sensitive of ''analytical methods'', the human body, can tell *immense* differences between the

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

two forms. The thalidomide tragedy in Europe in the 1960s is but one example. While one enantiomer of this compound was efficacious against morning sickness, the other was a teratogen, and since the compound was made as a racemic mixture, hundreds of children were born seriously deformed. The article **Chiral Separations by High-performance Liquid Chromatography** describes what we have learned, and what is left to accomplish.

A fundamental article, **Column Theory and Resolution in Liquid Chromatography**, describes the fundamental processes that occur inside the column, and the terminology that is used to describe the quality of separations.

Most real separations cannot be performed with a single composition mobile phase. That is, the range of solutes is so broad that any given mobile phase will be too ''strong'' for some solutes, providing little or no resolution, and will be too ''weak'' for others, letting them move through the column too slowly, if at all. The article **Gradient Elution Chromatography** describes this most used solution to the ''General Elution Problem'', and shows both theory and methodology for speeding separations.

While most people think of chromatography for the separation of neutral organic molecules, there is also much need for the analysis of charged species; from simple inorganic ions in plating plants and waste-treatment processes, to charged biopolymers. The article **Ion Chromatography** discusses the development of this very important chromatographic method, both in terms of separations but also in terms of detection of compounds that may have no chromophore.

Capillary electrophoresis is an efficient method for the separation of charged species that migrate in an applied electric field. **Micellar Electrokinetic Chromatography** describes an elegantly simple means of applying this technique for the separation of neutral species. Simply put, if a charged micelle can be made to remain more or less stationary in the electroosmotically flowing buffer, then neutral species will be separated based on differential partitioning to the micelle! This development opened entire new fields of separations.

Liquid chromatography uses organic solvents as components of the mobile phase. Driving forces for reduction of solvent use include environmental concerns and simply the economics of purchasing. **Microscale High-performance Liquid Chromatography and the Evolution of Capillary Electrochromatography** describes the miniaturization of the technique. Other advantages besides solvent savings exist as well, and the technique will slowly move in this direction.

The chemistry of the interaction of the solute with the mobile and stationary phases is how these elegant separations are developed. **Normal-phase Liquid Chromatography** uses a polar stationary phase and nonpolar liquid mobile phases for the separation of polar solutes. While this was the first method described by Tswett, usage of this method has dwindled but it is still a very powerful separation technique.

Reversed Phase Liquid Chromatography is by far the most practiced liquid separation method. The name arose from the reversal in elution order of most solutes compared to normal phase separations, and here a nonpolar stationary phase is used with polar mobile phases, typically water with an added polar organic solvent. Reversed-phase liquid chromatography is *the* workhorse method of the pharmaceutical industry.

The design of selective stationary phases is what allows the rapid, efficient separations that are achievable today. **Silica Gel and its Derivatization for Liquid Chromatography** describes how these phases are prepared, and offers challenges for better design of robust, reproducible phases.

While most analysts think of mobile phases as either gases or liquids, an almost 40-year-old technique exists using a mobile phase of a fluid taken above its critical point. **Supercritical Fluid Chromatography** describes this method, and shows the advantages offered when a fluid (mobile phase) has the solvating power of liquids, and diffusion coefficients closer to gases.

While column chromatography is a very powerful and often practiced method, one of its major limitations is that it is a ''serial'' technique. That is, one sample at a time is all that can be analyzed. **Thin-layer Chromatography** describes a liquid phase separation method performed on a flat plate, so that parallel ''lanes'' are possible, and separations can be run in parallel. While offering *far* lower resolving power than column methods, this is still a very heavily practiced method for the separation of simple mixtures, or for screening large numbers of samples.

Liquid chromatography is used for more than chemical analysis. The technique can be performed on both laboratory preparative scales and on industrial scales. Here the goal is *throughput*, the production of the greatest amount of pure material in the shortest time, and while the fundamentals of the separation process are essentially the same, the goal mandates that the operational aspects are quite different. Usually the sample (feed) is grossly overloaded onto the column, and the technique is referred to as *nonlinear chromatography*. Since an interfacial partitioning process is the most used mechanism of separation, the experiment can also be turned around, and the chromatography column can be used to *measure* these partitioning processes. Both thermodynamic and kinetic information can be obtained from a chromatography column.

Still, it is chemical analysis that drives further development of this technique. We will learn to better control the separation, we will learn to do it faster and with better limits of detection, but I doubt if we deviate much from the description of Tswett!

Affinity chromatography is a type of liquid chromatography that makes use of biological-like interactions for the separation and specific analysis of sample components. This article discusses the basic principles behind the theory and use of this method. Various factors that are important in the development of an affinity chromatographic system are considered, such as the choice of affinity ligand, support material, immobilization method, and elution conditions. A survey of the different types of affinity chromatography is also presented; this includes bioaffinity chromatography, immunoaffinity chromatography, dye–ligand affinity chromatography, immobilized metal affinity chromatography, and analytical affinity chromatography. In addition, some areas of expected future growth are considered, such as the use of molecular imprints or aptamers as ligands in affinity columns, and the coupling of affinity chromatography with other analytical techniques.

1 INTRODUCTION

1.1 Definition and Overview of Affinity Chromatography

Affinity chromatography is a liquid chromatographic technique that uses a well-defined binding agent as a stationary phase for the selective purification or analysis of sample components.[1–10] The retention of solutes in this method is generally based on the same types of specific, reversible interactions as those that occur in biological systems, such as the binding of an enzyme with a substrate or an antibody with an antigen. These interactions are used in affinity chromatography by immobilizing or adsorbing one of a pair of interacting molecules onto a solid support and placing this modified support into a column. The immobilized or adsorbed molecule that is used as the specific binding agent is known as the *affinity ligand*. The presence of this ligand results in a stationary phase that has the ability to bind to the complementary molecule in samples that are applied to the affinity column.

The wide range of selective ligands that are available in nature has made affinity chromatography a useful tool in areas such as biochemistry, pharmaceutical science, clinical chemistry, and environmental testing for the purification or analysis of compounds in complex sample mixtures. Because of the strong and relatively specific binding that characterizes many affinity ligands, solutes that are quantitated or purified by these ligands can often be separated with little or no interferences from other sample components. In many cases the solute of interest can be isolated in only one or two steps, with purification yields of one hundred- to several thousandfold being common.[2–5] Similar selectivity has been observed in numerous reports that have used affinity chromatography as an analytical tool for the detection and quantitation of specific compounds in such samples as serum, plasma, urine, foods, cell cultures, and water or soil extracts.[5,10,11]

1.2 History of Affinity Chromatography

The first reported use of affinity chromatography is generally recognized as having been in 1910, when Starkenstein used an insoluble starch support to purify the enzyme α-amylase.[12] There was some speculation in the mid-1920s about the value of using ''fixed partners'', or affinity ligands, as a general scheme for the isolation of biologically active compounds,[13] but there was little activity in this field for several decades after Starkenstein's work. In 1951, Campbell et al. were the first to use artificially immobilized ligands in an affinity column, when they attached antigens to diazotized *p*-aminobenzyl cellulose for the purification of antibodies.[14] After this work came several other applications, including reports

on the use of affinity chromatography for the purification of tyrosinase,[15] flavokinase,[16] and avidin.[17]

However, affinity chromatography did not see widespread use until the late 1960s. It was during this time period that there were several important developments that led to a greater flexibility and ease of use for affinity methods. One of these breakthroughs involved the introduction of better supports for affinity chromatography, such as beaded agarose.[18] Another development that came about at this time was a report on the CNBr method for coupling proteins and other ligands to affinity supports through primary amine groups.[19] Both of these advances were used in 1968 by Cuatrecasas, Wilchek, and Anfinsen to produce what are now considered the first ''modern'' affinity chromatographic separations.[20]

Beginning in the 1970s, affinity chromatography saw rapid growth as a purification tool for biochemicals,[1–10] but most of this work continued to employ soft gels like agarose for the affinity support.[5,10] These gels tended to limit the usefulness of affinity chromatography as an analytical tool because of their ability to work at only relatively low flow-rates and operating pressures which, in turn, resulted in fairly long run times.[5,10] More rapid separations were made possible by the development of alternative supports, such as the diol-bonded silica matrix reported in 1976 by Regnier and Noel.[21] These newer materials could withstand the same pressures and flow-rates as used in high-performance liquid chromatography (HPLC) but still provided a surface that could be modified for ligand attachment and that provided low nonspecific binding for most biological compounds.[5,10] In 1978, Ohlson et al. combined these HPLC-compatible materials with affinity ligands to produce a method known as high-performance affinity chromatography (HPAC).[22] It was this approach that now made it more feasible to use affinity chromatography as an analytical tool for the characterization of biological and non-biological samples.[5,10]

Figure 1 (a) Typical separation scheme for affinity chromatography and (b) a representative model chromatogram. The open circles represent the test analyte and the squares represent other, nonretained sample components. (Reproduced by permission of the Clinical Ligand Assay Society from D.S. Hage, *J. Clin. Ligand Assay*, **20**, 293–301 (1997).[48])

2 THEORY OF AFFINITY CHROMATOGRAPHY

The most common method used for performing affinity chromatography is a step-wise elution scheme, as shown in Figure 1. In this approach, a sample containing the compound of interest is injected onto the affinity column in the presence of a mobile phase that has the right pH, ionic strength, and solvent composition for solute-ligand binding. This solvent, which represents the weak mobile phase of the affinity column, is called the *application buffer*. As the sample passes through the column in the application buffer, compounds which are complementary to the affinity ligand will bind. However, owing to the high selectivity of this interaction, other solutes in the sample will tend to elute from the column nonretained. After all nonretained components have been washed from the column, the retained solutes are then eluted by applying a solvent that displaces them from the column or that promotes dissociation of the solute–ligand complex. This solvent, which represents the strong mobile phase for the column, is known as the *elution buffer*. As the solutes of

interest elute from the column, they are either measured directly or collected for later use. The application buffer is then reapplied to the system and the column is allowed to regenerate prior to the next sample injection.[5,10]

A number of factors are important in determining the retention and elution of a compound in an affinity column. These factors include the strength of the solute–ligand interaction, the amount of immobilized ligand present in the column, and the kinetics of solute–ligand association and dissociation. In the case where a solute (A) has single-site binding to a ligand (L), Equations (1–3) can be used to describe the interactions between the solute and ligand in an affinity column.

$$A + L \underset{k_d}{\overset{k_a}{\rightleftharpoons}} A - L \tag{1}$$

$$K_a = \frac{k_a}{k_d} \tag{2}$$

$$= \frac{\{A - L\}}{[A]\{L\}} \tag{3}$$

In these relationships, K_a is the association equilibrium constant for the binding of A with L, A–L is the resulting solute–ligand complex, [A] is the mobile phase concentration of A at equilibrium, and {L} or {A–L} represent the surface concentrations of the ligand or solute–ligand complex, respectively. The term k_a is the second-order association rate constant for solute–ligand binding and k_d is the first-order dissociation rate constant for the solute–ligand complex. At equilibrium, the retention of solute in the above system can be described by Equations (4) and (5),

$$k = \frac{K_a m_L}{V_M} \tag{4}$$

$$= \left(\frac{t_R}{t_M} \right. - 1 \tag{5}$$

where k is the retention factor for the injected solute, t_R is the solute's retention time, and t_M is the void time of column.[10,23] The term m_L represents the moles of active ligand in column and V_M is the column void volume.

Equations (4) and (5) indicate that the retention factor for a solute, or its retention time, will depend on both the strength of solute–ligand binding (i.e. the association equilibrium constant, K_a) and the amount of ligand in the column (i.e. m_L/V_M). This retention factor is often very large in the presence of the application buffers that are used in affinity chromatography. For instance, affinity columns that contain polyclonal antibodies as ligands (which generally have K_a values in the range of 10^8–$10^{10}\ M^{-1}$) can give rise to retention factors of 10^3 or greater under physiological conditions.[10] The only way in which solutes can be eluted from these columns in a reasonable amount of time is to lower the effective value of K_a for solute–ligand binding; in fact, this is the main role of the elution buffer for an affinity column.

Although the step gradient, or "on/off", elution mode shown in Figure 1 is the most common way of performing affinity chromatography, it is also possible to carry out affinity methods by using isocratic elution. This second approach can be employed if the value of a solute's association equilibrium constant (and retention factor) for the column are sufficiently small to allow elution on the minute-to-hour time scale. Fast association and dissociation kinetics are also desirable in this mode in order to allow a large number of solute–ligand interactions to occur as an analyte travels through the column, thus producing good plate heights and narrow peaks. This approach, sometimes called *weak-affinity chromatography*, is fairly easy to perform if a solute's K_a value is less than or equal to $10^4\ M^{-1}$, and has even been employed on some systems with association constants up to $10^6\ M^{-1}$.[24–26]

3 BASIC COMPONENTS OF AFFINITY SYSTEMS

3.1 Affinity Ligands

The key factor in determining the success of any affinity separation is the type of ligand that is used within the column. A number of ligands that are commonly used in affinity chromatography are listed in Table 1. Many of these ligands are of biological origin, but a wide range of natural and synthetic molecules of nonbiological origin can also be used. However, all of these compounds can be placed into one of two categories: (1) high-specificity ligands and (2) general, or group specific, ligands.[5,10]

The term *high-specificity ligands* refers to compounds which bind to only one or a few closely related molecules. This type of ligand is used in chromatographic systems where the goal is to analyze or purify a specific solute. Typical high-specificity ligands include antibodies (for binding antigens), substrates or inhibitors (for separating enzymes), and single-stranded nucleic acids (for the retention of a complementary sequence). As this list suggests, most high-specificity ligands tend to be biological compounds. These ligands also tend to have relatively large association constants for solutes and are generally eluted by a step gradient.

General, or group-specific, ligands are compounds that bind to a family or class of related molecules. These ligands are used in methods where the goal is to isolate a class of structurally similar solutes. General ligands can be of either biological or non-biological origin. Examples given in Table 1 include proteins A and G, lectins, boronates, triazine dyes, and immobilized metal chelates.

Table 1 Common ligands used in affinity chromatography

Type of ligand	Examples of retained compounds
High-specificity ligands	
Antibodies: Monoclonal or polyclonal antibodies, Fab fragments, $F(ab)_2$ fragments, or related antibody fragments	Complementary antigens, such as drugs, hormones, peptides, proteins, viruses, cell components, and pesticides
Enzyme-binding agents: Inhibitors, substrates, coenzymes, cofactors, anti-enzyme antibodies	Complementary enzymes
Nucleic acids: Single-stranded DNA or RNA, double-stranded DNA or RNA, nucleotides	Complementary nucleic acids, DNA/RNA-binding proteins or enzymes
General ligands	
Lectins: Concanavalin A, wheat germ agglutinin, jacalin, lectins from lentil, pea, peanut, and soybean, lectins 60 and 120 from *Ricinus communis*, phytohemagglutinins E_4 and L_4	Small sugars, polysaccharides, glycoproteins, glycolipids, glycoconjugates
Antibody-binding proteins: Protein A, protein G, protein A/G, protein B, mannan-binding protein	Intact antibodies and Fc fragments
Boronates: Boronic acid, phenylboronic acid	Sugars and polysaccharides, catechols, glycoproteins, glycolipids, glycoconjugates
Synthetic dyes: Cibacron Blue F3GA, Procion Blue MX-3B, Procion Blue MX-R, Procion Red HE-3B, thymol blue, phenol red	Dehydrogenases, kinases, albumin, α-fetoprotein, CoA-dependent enzymes, hydrolases, nucleases, polymerases, synthetases, transferases, immunoglobulin G
Metal chelates: Metal complexes of imino-diacetic acid, carboxymethylaspartic acid, tris-carboxymethylethylenediamine, tris(2-aminoethyl)amine, or dipicolylamine	Metal-binding amino acids, peptides, and proteins

Many of the compounds have weaker binding for solutes than that seen with high-specificity ligands; however, there are exceptions to this. For example, protein A has an equilibrium association of over $10^8\ M^{-1}$ for some types of antibodies.[27] Also, some molecules which are usually considered to be high-specificity ligands, such as antibodies, can be used to retain an entire class of solutes if they recognize a feature that is common to all of the desired analytes.[11,28]

3.2 Support Materials

Another important factor to consider in affinity chromatography is the material used to hold the ligand within the column. Table 2 lists some examples of common supports found in affinity columns. Ideally, this support material should have low nonspecific binding for sample components but should be easy to modify for ligand attachment. This material should also be stable under the flow-rate, pressure, and solvent conditions to be employed in the analysis or purification of samples. In addition, the support should be readily available and simple to use in method development.[1–10]

Table 2 Common support materials used in affinity chromatography[8,10]

Carbohydrate-based supports	Agarose and cross-linked agarose; cellulose and modified cellulose
Modified inorganic supports	Controlled-porosity glass; glass beads; silica
Synthetic organic-based supports	Agarose/acrylamide copolymers; azalactone beads (Emphaze™); dextran/acrylamide copolymers; hydroxylated polystyrene perfusion media (POROS™); polyacrylamide derivatives; polyethersulfone matrix; polymethacrylate derivatives

Depending on what type of support material is being used, affinity chromatography can be characterized as either a low- or high-performance technique. In *low-performance (or column) affinity chromatography*, the support is usually a large-diameter, nonrigid gel. Many of the carbohydrate-based supports and synthetic organic materials listed in Table 2 fall within this category. An example of a separation based on low-performance affinity chromatography is shown in Figure 2. The low back-pressure of these supports means that they can often be operated under gravity flow or with a peristaltic pump. This makes these gels relatively simple and inexpensive to use for affinity purifications. Disadvantages of these materials include their slow mass transfer properties and their limited stability at high flow-rates and pressures. These factors limit the usefulness of these supports in analytical applications, where both rapid and efficient separations are often desired.[5,10]

In HPAC, the support consists of small, rigid particles capable of withstanding the high flow-rates and/or pressures that are characteristic of HPLC.[5,10,22] Examples of affinity supports that are suitable for work under these conditions include modified silica or glass, azalactone beads, and hydroxylated polystyrene media. The mechanical stability and efficiency of these supports allows them to be used with standard HPLC equipment. Although the need for more sophisticated instrumentation does make HPAC more expensive to perform than low-performance affinity chromatography, the better speed and precision of this technique makes it the method of choice for analytical applications,[5,10,11] such as that shown in Figure 3.

Figure 2 Example of a separation of lactate dehydrogenase (LDH) isoenzymes by low-performance affinity chromatography on an immobilized AMP-analog column and in the presence of a mobile phase gradient of increasing NADH concentration. (Reprinted from P. Brodelius, K. Mosbach, 'Separation of the Isoenzymes of Lactate Dehydrogenase by Affinity Chromatography using an Immobilized AMP-analogue', *FEBS Lett.*, **35**, 223–226, Copyright (1973), with permission from Elsevier Science.)

Figure 3 High-performance affinity chromatographic separation of concanavalin A (peak 2) from bovine serum albumin (peak 1) on an immobilized glucosamine column. The concanavalin A was eluted by applying at the arrow an elution buffer that contained methyl α-D-mannopyranoside. (Reprinted from R.R. Walters, 'High-performance Affinity Chromatography', *Trends Anal. Chem.*, **2**, 282–285, Copyright (1983), with permission from Elsevier Science.)

3.3 Immobilization Methods

A third item to consider in using affinity chromatography is the way in which the ligand is attached to the

solid support, or the *immobilization method*. Several techniques are available for this (see Table 3). For a protein or peptide, this generally involves coupling the molecule through free amine, carboxylic acid, or sulfhydryl residues present in its structure. Immobilization of a ligand through other functional sites (e.g. aldehyde groups produced by carbohydrate oxidation) is also possible. All immobilization methods involve at least two steps: (1) an *activation step*, in which the support is converted to a form that can be chemically attached to the ligand, and (2) a *coupling step*, in which the affinity ligand is attached to the activated support. With some techniques a third step, in which remaining activated groups are removed, is also required.[8,10]

The choice of immobilization method is important since it can affect the actual or apparent activity of the final affinity column. If the correct procedure is not used, a decrease in ligand activity can result from multisite attachment, improper orientation and/or steric hindrance (see Figure 4). *Multisite attachment* refers to the coupling of a ligand to the support through more than one functional group, which can lead to distortion and denaturation of the ligand's active region. This effect can be minimized by coupling the ligand through functional groups that occur in only a few places in its structure or by using a support with a low density of activated sites. *Improper orientation* can also lead to a loss in ligand activity but can be avoided by coupling the ligand through groups that are distant from its active region. If the actual location of the ligand's active site is not known or if no appropriate functional groups are available, it is sometimes possible to minimize this problem by empirically varying the procedure or conditions used for ligand attachment. *Steric hindrance* refers to the loss of ligand activity due to the presence of a nearby support or neighboring ligand molecules.[5] Steric hindrance produced by neighboring ligands can be minimized by using a low ligand coverage, while steric hindrance produced by the support can be reduced by adding a *spacer arm*, or tether, between the ligand and supporting material. The presence of a spacer arm is particularly important when using small ligands for the retention of large analytes. Examples of common spacer arms used in affinity chromatography include 6-aminocaproic acid, diaminodipropylamine, 1,6-diaminohexane, ethylenediamine and succinic anhydride.[8]

Figure 4 Illustration of multisite attachment, improper orientation, and steric hindrance effects in affinity chromatography.

Table 3 Immobilization methods for affinity chromatography[8,10]

Amine-reactive coupling techniques
Azalactone method (for Emphaze™); CNBr method; CDI method; divinylsulfone method; epoxy (bisoxirane) method; EDC method; FMP method; NHS method; Schiff base (reductive amination) method; tresyl chloride/tosyl chloride method
Sulfhydryl-reactive coupling techniques
Azalactone method (for Emphaze™); divinylsulfone method; epoxy (bisoxirane) method; iodoacetyl/bromoacetyl methods; maleimide method; pyridyl disulfide method; TNB-thiol method; tresyl chloride/tosyl chloride method
Carboxylate-reactive coupling techniques
EDC method
Hydroxyl-reactive coupling techniques
Cyanuric chloride method; divinylsulfone method; epoxy (bisoxirane) method
Aldehyde-reactive coupling techniques
Hydrazide method; Schiff base (reductive amination) method
Nucleic acid-coupling techniques
CDI method; carboxymethyl method (for cellulose); CNBr method; cyanuric chloride method; diazonium (azo) method; epoxy (bisoxirane) method; hydrazide method (for RNA); on-support synthesis; Schiff base (reductive amination) method (for RNA); UV irradiation (for cellulose)

CNBr, cyanogen bromide; CDI, *N*,*N*′-carbonyl diimidazole; EDC, ethyldimethylaminopropyl carbodiimide; FMP, fluoro methylpyridinium toluenesulfonate; NHS, *N*-hydroxysuccinimide ester; UV, ultraviolet.

3.4 Application and Elution Conditions

The application buffer is another parameter that must be considered in the use of an affinity column. Most application buffers in affinity chromatography are solvents that mimic the pH, ionic strength and polarity experienced by the solute and ligand in their natural environment. Any cofactors or metal ions required for solute–ligand binding should also be present in this solvent. Under these conditions, the solute will probably have its highest association constant for the ligand and its highest degree of retention on the column. The proper choice of the application buffer can also help to minimize any nonspecific binding due to undesired sample components. For example, coulombic interactions between

solutes and the support can often be decreased by altering the ionic strength and pH of the application buffer. In addition, surfactants and blocking agents may be added to the buffer to prevent nonspecific retention of solutes on the support or affinity ligand.

The activity of the immobilized ligand should be considered in determining how much sample can be applied to the affinity column with each use. A rough indication of the maximum possible column binding capacity can be made by assaying the total amount of ligand present or by actually measuring the ligand's binding activity. With some affinity systems, it is possible to see a large amount of nonretained solute during the application step even when the amount of injected sample is significantly less than known column binding capacity.[29] This phenomenon, known as the *split-peak effect*, is caused by the presence of slow adsorption and/or mass transfer kinetics within the column (see Figure 5). This effect has been reported with many types of affinity ligands,[29–33] but tends to occur with high-performance supports because of the more rapid flow-rates often used with these materials. Ways in which this effect can be minimized include reducing the flow-rate used for sample injection, increasing the column size, or placing a more efficient support within the column. In some cases, changing the immobilization method may help by providing a ligand with more rapid binding kinetics.[29]

Figure 5 Nonretained (or free) fractions observed in split-peak measurements for the injection of rabbit immunoglobulin G onto a protein G affinity column at various sample application flow-rates. The top chromatogram shows the elution of rabbit immunoglobulin G on a column containing only diol-bonded silica, which has no binding for this analyte. (Reprinted from J.G. Rollag, D.S. Hage, *J. Chromatogr. A*, **795**, 185–198, Copyright (1998), with permission from Elsevier Science.[33])

The conditions used for removal of retained solutes is another item that should be considered in the design of an effective affinity separation. Just as the application conditions are selected to maximize specific solute–ligand interactions, the elution conditions are chosen to promote fast or gentle removal of solute from the column. The elution buffer used in affinity chromatography can be either a solvent that produces weak solute–ligand binding (i.e. a small association equilibrium constant) or a solvent that decreases the extent of this binding by using a competing agent that displaces solute from the column. These two approaches are known as *nonspecific elution* and *biospecific elution*, respectively.[5]

Biospecific elution is the gentler of these two elution methods since it is carried out under essentially the same solvent conditions as are used for sample application. This makes this approach attractive for purification work, where a high recovery of active solute is desired. Biospecific elution may be performed either by adding an agent to the eluting solvent that competes with the ligand for solute (i.e. *normal role elution*) or by adding an agent that competes with solute for ligand-binding sites (i.e. *reversed-role elution*). In both cases, retained solutes are eventually eluted from the column by displacement and mass action. The main advantage of biospecific elution is its ability to gently remove analyte from the column. The main disadvantages are the slow elution times and broad solute peaks that are typically produced by this approach. Other limitations in purification work include the need to remove the competing agent from the final fraction of eluted solute and, in analytical applications, the need to use a competing agent that does not produce a large background signal under the conditions used for analyte detection.

In nonspecific elution, the solute is eluted by changing the column conditions in order to weaken the interactions between any retained compounds and the immobilized ligand. This can be done by changing the pH, ionic strength, or polarity of the mobile phase. The addition of denaturing or chaotropic agents to the running buffer can also be used. This results in an alteration in the structure of the solute or ligand, leading to a lower association equilibrium constant and lower solute retention. Nonspecific elution tends to be much faster than biospecific elution in removing analytes from affinity columns. This results in sharper peaks, which in turn produces lower limits of detection and shorter analysis times. For these reasons, nonspecific elution is commonly used in analytical applications of affinity chromatography. This elution method can also be used in purifying solutes, but there is a greater risk of solute denaturation with this approach than there is with biospecific elution. Furthermore, care must be taken in nonspecific elution to avoid using conditions that are too harsh for the

column. If this is not considered, it may result in long column regeneration times or an irreversible loss of ligand activity.

4 TYPES OF AFFINITY CHROMATOGRAPHY

4.1 Bioaffinity Chromatography

Bioaffinity chromatography, also known as *biospecific adsorption*, is a name that is used to describe affinity methods that use a biological molecule as the affinity ligand. This was the first type of affinity chromatography that was developed and continues to represent the most diverse category of this technique. As stated earlier, the first use of bioaffinity chromatography was in 1910 when Starkenstein purified α-amylase using insoluble starch (a substrate for this enzyme) as both the support and affinity ligand.[12] Further examples of ligands that are used in bioaffinity chromatography are provided in Table 1.

The use of bioaffinity chromatography for enzyme purification, as originally reported by Starkenstein, continues to be an important and common use of this method. The importance of this field is illustrated by a review which cites several hundred applications in this area alone.[34] An example of an enzyme separation performed by bioaffinity chromatography is shown in Figure 2. Ligands that can be used for this purpose include enzyme inhibitors, coenzymes, substrates, and cofactors. For instance, nucleotide mono-, di-, and triphosphates can be used for the purification of various kinase enzymes, NAD has been used to isolate dehydrogenases, pyridoxal phosphate has been employed for the purification of tyrosine and aspartate aminotransferases, and RNA or DNA has been used for the collection of polymerases and nucleases.[4] Antibodies that specifically bind to certain enzymes are also commonly used in such purification schemes.[34,35]

Lectins represent a class of general ligands that are common in bioaffinity chromatography. The term *lectin affinity chromatography* is sometimes used to refer to the resulting separation method. Lectins are non-immune system proteins, generally of plant origin, that have the ability to recognize and bind certain types of carbohydrate residues.[36] Some of the most common lectins that are used in affinity chromatography include concanavalin A (which binds to α-D-mannose and α-D-glucose residues), wheat germ agglutinin (which binds to D-*N*-acetylglucosamines) and jacalin (which binds to α-D-galactose residues). Other lectins that are also used are listed in Table 4. These ligands are valuable in the separation of many carbohydrate-containing compounds, such as polysaccharides, glycoproteins (e.g. immunoglobulins or cell membrane proteins), glycolipids and other types of glycoconjugates.[1–4,8,10]

Table 4 Examples of carbohydrate residues that bind to lectins used in affinity chromatography[8]

Carbohydrate residue	Types of interacting lectins
D-*N*-Acetyl galactosamine	Lectin 60 from *Ricinus communis*, soybean lectin (Note: phytohemagglutinins E_4 and L_4 also bind to *N*-acetyl galactosamines)
α-D-Galactose	Jacalin (Note: peanut and soybean lectin also bind to D-galatose)
β-D-Galactose	*Ricinus communis* lectins 60 and 120
α-D-Glucose	Concanavalin A, lentil lectin, pea lectin
α-D-Mannose	Concanavalin A, lentil lectin, pea lectin

Another useful class of bioaffinity ligands are antibody-binding proteins. Two common examples of these are protein A, a bacterial cell wall protein from *Staphylococcus aureus*, and protein G, which is a cell wall protein from group G streptococci bacteria.[27,37,38] These ligands have the ability to bind to the constant region of many types of immunoglobulins, or antibodies. This makes them useful in antibody purification, particularly when dealing with IgG-class antibodies.[8] Protein A and protein G have their strongest binding to immunoglobulins at or near neutral pH but readily dissociate from these solutes when placed into a lower pH buffer. These two ligands differ in their ability to bind to antibodies from different species and classes.[27,39] Recombinant versions of both protein A and protein G are available commercially[8] along with a recombinant fusion protein, known as protein A/G, that blends the binding activities of these two ligands.[40]

Other examples of antibody-binding proteins include protein B and mannan-binding protein. Protein B is a b antigen protein found on the surface of group A streptococci bacteria. It is useful in binding to several types of IgA-class antibodies, such as human IgA_1, IgA_2 and secretory IgA. However, it does not bind to mouse IgA or IgAs from many other types of mammals.[8,41] Mannan-binding protein is found in the serum of various mammals[42] and has been found to bind IgM-class antibodies in mouse ascites fluid, making it of potential use for the isolation of IgM monoclonal antibodies.[43] The binding of antibodies to mannan-binding protein is calcium-dependent and the elution of bound IgM can be obtained by incorporating ethylene diamine tetraacetic acid (EDTA) as a calcium-complexing agent into the mobile phase.[8]

Nucleic acids and polynucleotides can act as either general or specific ligands in bioaffinity chromatography.[44,45]

For instance, as high-specificity ligands they can be used to purify DNA/RNA-binding enzymes and proteins or to isolate nucleic acids that contain a sequence which is complementary to the ligand.[46] As a group-specific ligand, an immobilized nucleic acid can be used to purify solutes that share a common nucleotide sequence. An example is the use of immobilized oligo(dT) for the isolation of nucleic acids containing poly(A) sequences. As mentioned earlier, another example of a general nucleic acid ligand is the use of nucleotide mono-, di-, and triphosphates for the purification of kinase enzymes.[4]

4.2 Immunoaffinity Chromatography

Immunoaffinity chromatography (IAC) is a special category of bioaffinity chromatography in which the ligand that is used is an antibody or antibody-related reagent.[10,11,35] Other methods that are sometimes included under the heading of IAC are those that use immobilized antigens or antibody-binding proteins for antibody purification.[8,11,47] The first known use of IAC was the work described earlier by Campbell et al. in 1951.[14] Many current applications are still based on the use of low-performance supports, particularly agarose.[35] However, recent work has also been performed using derivatized silica, glass, and perfusion media. The use of these supports along with an antibody or antigen ligand is referred to as *high-performance immunoaffinity chromatography* (HPIAC).[11,47,48]

The high selectivity of antibody–antigen interactions and the ability to produce antibodies against a wide range of solutes has made IAC a popular tool for biological purification and analysis. There are now literally hundreds to thousands of examples of immunoaffinity methods that have been developed for the isolation of antibodies, hormones, peptides, enzymes, recombinant proteins, receptors, viruses, and subcellular components.[34,35,47,49–53] The high association equilibrium constants of many antibodies requires that nonspecific elution be used with most immunoaffinity columns.[47] However, isocratic elution methods can also be used with low-affinity antibody systems.[24]

The use of IAC in analytical methods has also received a great deal of attention in recent years.[11,48] Table 5 summarizes some strategies that can be employed in these analyses and gives some examples of representative applications. The simplest format for using IAC in compound analysis involves the traditional ''on/off'' or step-gradient mode of affinity chromatography (see Figure 1). The advantages of using this approach in analytical applications, particularly when performed by HPIAC, include its relative simplicity, good precision, and potential for fast sample analysis. One requirement of the direct detection mode is that there must be some way to monitor the analyte as it leaves the column. For protein solutes, UV absorbance measurements at 210–215 nm or 280 nm are most commonly used. In some cases minor sample components have been monitored by using precolumn derivatization to place easy-to-detect labels (such as fluorescent tags) on sample solutes prior to injection. Another alternative is to collect fractions of the column eluent and later analyze these by a separate technique, such as an immunoassay or assay for biological activity.[11]

Immunoextraction is another approach by which immunoaffinity columns can be used for solute detection. In this method, an immunoaffinity column is used for the removal of a specific solute or group of solutes from a sample prior to determination by a second analytical method. This employs the same general operating scheme as shown in Figure 1, but now involves combining the immunoaffinity column either off-line or on-line with some other method for the actual quantitation of analytes. Off-line methods are generally the easiest and most common way for combining immunoaffinity columns with other analytical techniques.[11,54–57] This approach typically involves the use of antibodies that are immobilized onto a low-performance support that is packed into a small disposable syringe or solid-phase extraction cartridge. After conditioning the immunoaffinity column with the necessary application buffer or conditioning solvents, the sample is applied and undesired sample components are washed away. An elution buffer is then applied and the test analyte is collected as it is removed from the column. If desired, the collected fraction can be analyzed directly or first dried down and reconstituted in a solvent that is compatible with the analytical method to be used for quantitation (e.g. HPLC or gas chromatography (GC)).

The fact that off-line immunoextraction generally involves manual sample preparation does limit the potential speed and precision of this approach. To overcome this problem, a large number of recent reports have examined the use of on-line immunoextraction methods. The direct coupling of immunoextraction with HPLC has been of particular interest,[11,28] but some methods have also been reported that involve the coupling of on-line immunoextraction with GC[58] or capillary electrophoresis.[59–61] A typical column switching scheme for performing on-line immunoextraction with reversed-phase liquid chromatography (RPLC) is shown in Figure 6.[48] The general format for this type of system involves injecting the sample onto the immunoaffinity extraction column, with the nonretained components being allowed to go to a waste container. The immunoaffinity column is then switched on-line with a RPLC column and an elution buffer is applied to the immunoaffinity support to dissociate any retained analyte. As these analytes elute, they are captured and

Table 5 Examples of analytical applications of IAC[11]

Direct analyte detection
Anti-idiotypic antibodies, antithrombin III, bovine growth hormone, fibrinogen, fungal carbohydrate antigens, glucose tetrasaccharide, glutamine synthetase, granulocyte colony stimulating factor, group A-active oligosaccharides, human serum albumin, immunoglobulin G, immunoglobulin E, interferon, interleukin-2, lymphocyte receptors, β_2-microglobulin, tissue-type plasminogen activator, transferrin
Off-line immunoextraction
HPLC Methods: Aflatoxin, albuterol, benzodiazepines, cytokinins, fumonisin, human chorionic gonadotropin, ivermectin and avermectin, nortestosterone, ochratoxin A, oxytocin, phenylurea herbicides, sendai virus protein, trenbolone, triazine herbicides
GC Methods: Alkylated DNA adducts, chloramphenicol, dexamethasone, estrogens, flumethasone, nortestosterone, prostaglandins and thromboxanes
On-line immunoextraction
HPLC Methods: Aflatoxin M1, β-agonists, α1-antitrypsin, atrazine, atrazine metabolites, benzylpenicilloyl-peptides, bovine serum albumin, carbendazim, carbofuran, chloramphenicol, clenbuterol, cortisol, dexamethasone, diethylstilbestrol, digoxin, estrogens, hemoglobin, human epidermal growth factor, human growth hormone variants, interferon α-2, LSD and metabolites, lysozyme variants, 17β- and 17α-19-nortestosterone, phenytoin, propranolol, Δ9-tetrahydrocannabinol, tolubuterol, transferrin, 17β- and 17α-trenbolone
GC Methods: β-19-Nortestosterone and related steroids
Capillary Electrophoresis Methods: Cyclosporin, immunoglobulin E, insulin
Chromatographic immunoassays
Competitive binding immunoassays: Adrenocorticotropic hormone, α-amylase, atrazine/triazines, 2,4-dinitrophenyl lysine, human chorionic gonadotropin, human serum albumin, immunoglobulin G, isoproturon, testosterone, theophylline, thyroid stimulating hormone, thyroxine, transferrin, trinitrotoluene
Sandwich immunoassays: Anti-bovine IgG antibodies, human serum albumin, immunoglobulin G, interferon, parathyroid hormone
One-site immunometric assays: α-(Difluoromethyl)ornithine, 17-β-estradiol
Post-column immunodetection
Acetylcholinesterase, bovine growth hormone releasing factor, digoxin, digoxigenin, digoxin metabolites, human methionyl granulocyte colony stimulating factor

reconcentrated at the head of the RPLC column. After all solutes have left the immunoaffinity column, this column is then switched back off-line and regenerated by passing through the initial application buffer. Meanwhile, the RPLC column is developed with either an isocratic or gradient elution scheme involving the application of a mobile phase with an increased organic modifier content. As the solutes elute through the RPLC columns, they are then monitored and quantitated at an on-line detector.[11]

A third area that has received increasing attention in recent years has been the use of IAC to perform various types of *chromatographic* (or *flow-injection*) *immunoassays*.[11,48] This is particularly valuable in determining trace analytes that, by themselves, may not produce a readily detectable signal. The competitive binding assay is the most common format that has been used in performing these immunoassays. One way this can be done is to mix the sample with a labeled analyte analog (i.e. the ''label'') and simultaneously inject these onto an immunoaffinity column that contains a relatively small amount of antibody; this method is known as a *simultaneous injection competitive binding immunoassay*. An alternative format, known as a *sequential injection competitive binding immunoassay*, involves the application of only sample to the immunoaffinity column, followed later by a separate injection of the label (see Figure 7a). In either case, the analyte competes with the injected label for the antibody binding sites in the column, thus making the amount of label that elutes in either the retained or nonretained fractions an indirect measure of how much analyte was present in the original sample.

Sandwich immunoassays and one-site immunometric assays have also been performed as part of immunoaffinity systems.[11,48] In the sandwich immunoassay (Figure 7b), two different types of antibodies are used that each bind to the analyte of interest. The first of these two antibodies is attached to a solid-phase support and is

Figure 7 Schemes for chromatographic immunoassays based on (a) a sequential injection competitive binding format and (b) a sandwich immunoassay format. (Reprinted with permission from D.S. Hage, P.C. Kao, 'Theory of a Sequential Addition Competitive Binding Immunoassay Based on High-performance Immunoaffinity Chromatography', *Anal. Chem.*, **63**, 586–595, Copyright (1991), American Chemical Society, and D.S. Hage, D.H. Thomas, M.S. Beck, *Anal. Chem.*, **65**, 1622–1630, Copyright (1993), American Chemical Society.[32])

used to extract the analyte from samples. The second antibody contains an easily measured tag and is added in solution to the analyte either before or after this extraction; this second antibody serves to place a label onto the analyte, thus allowing the amount of analyte on the immunoaffinity support to be quantitated. In the one-site immunometric assay, the sample is first incubated with a known excess of labeled antibodies or Fab fragments that are specific for the analyte of interest. After binding between the sample analyte and antibodies has occurred, this mixture is then applied to a column that contains an immobilized analog of the analyte. This column serves to extract any antibodies or Fab fragments that are not bound to sample analyte. Meanwhile, those antibodies or Fab fragments that are bound to sample analyte will pass through the column in the nonretained peak. Detection is then performed by looking at the size of the nonretained peak for the labeled antibodies/Fab fragments.

Yet another way in which immunoaffinity columns can be used is for monitoring the elution of specific solutes from other chromatographic columns, a technique known as *post-column immunodetection*. This involves the use of a post-column reactor and an immobilized antibody or antigen column attached to the exit of an analytical HPLC column.[11,62] This can be performed by either using the on/off direct detection mode of IAC or chromatographic immunoassay formats based on one-site immunometric assays, sandwich immunoassays or competitive-binding immunoassays.[11,48] The one-site immunometric assay is the most common format for immunodetection.[11] The basic operation involves taking the analytical HPLC column eluent and combining this with a solution of labeled antibodies or Fab fragments that will bind the analyte of interest. The column eluent and antibody or Fab mixture is then allowed to react in a mixing coil and passed through an immunodetection column that contains an immobilized analog of the analyte. The antibodies or Fab fragments that are bound to the analyte will pass through this column and onto the detector, where they will provide a signal that is proportional to the amount of bound analyte. If desired, the immunodetection column can later be washed with an eluting solvent to dissociate the retained antibodies or Fab fragments; but a sufficiently high binding capacity is generally used so that a reasonably large amount of analytical column eluent can be analyzed before the immunodetection column must be regenerated.

4.3 Dye-ligand Affinity Chromatography

Another category of affinity chromatography is the technique known as *dye-ligand affinity chromatography*. The first use of dye-ligand affinity chromatography was described in 1974.[63] Since that time it has become an extremely popular tool for enzyme and protein purification,[1–4,8,10,63–65] with over 500 such compounds having been isolated by this technique.[5] In this method, a synthetic dye (like a triazine or triphenylmethane compound) is used as the immobilized ligand (see Figure 8). These dyes bind to the active site of a protein or enzyme by mimicking the structure of a substrate or cofactor for that biomolecule. The most common dye used for this purpose is Cibacron Blue F3G-A. Some other examples of dyes that are used as ligands in affinity chromatography include Procion Blue MX-3G or MX-R, Procion Red HE-3B, thymol blue and phenol red.[8]

The cibacron and procion dyes all have a chlorotriazine ring but have different side groups attached to this ring. For Cibacron Blue F3G-A, one of these side groups is an anthraquinone that reacts with enzymes that have a binding site for NAD, NADP or ATP. This property

Figure 8 Structures of some common ligands used in dye-ligand affinity chromatography. (a) Cibacron Blue F3GA. (b) Procion Red HE3B.

makes this dye useful as a ligand for the purification of dehydrogenases, kinases, and other enzymes that require such cofactors. However, this same dye can also be used for a wide range of other enzymes and proteins. Examples include albumin, α-fetoprotein, CoA-dependent enzymes, hydrolases, immunoglobulin G, lipoproteins, nucleases, polymerases, synthetases and transferases.[64,65] The other dyes used in dye-ligand affinity chromatography have slightly different specificities, but can similarly be used for the purification of variety of enzymatic and nonenzymatic proteins.[8]

4.4 Immobilized Metal Ion Affinity Chromatography

In *immobilized metal ion affinity chromatography* (*IMAC*), or *metal chelate affinity chromatography*, the affinity ligand is a metal ion which is complexed with an immobilized chelating agent. This type of affinity chromatography was first described by J. Porath and co-workers in 1975.[66] It was initially used to separate proteins and peptides that contained amino acids with electron donor groups (such as histidine, tryptophan, or cysteine) with the proteins and peptides being retained owing to interactions between their amino acids and the immobilized metal chelate.[66,67] Since its discovery, a number of peptides, proteins, and amino acids have been purified by this method. An example of one such separation is shown in Figure 9.

Selectivity in IMAC is determined by the chelating group and the type of metal ion that is used to make up the affinity ligand. Iminodiacetic acid is the most common chelating agent employed. Other ligands that are used in IMAC include carboxymethylaspartic acid, tris-carboxymethylethylenediamine, tris(2-aminoethyl)amine and dipicolylamine.[66–68] Metal ions used with these chelating groups include Cu^{2+}, Zn^{2+}, Ni^{2+}, Co^{2+}, and Fe^{3+}.[68] In general, the stronger that the interaction is between the metal ion and the chelating group, the weaker the observed retention will be between the same immobilized metal and an injected protein or peptide.

4.5 Analytical Affinity Chromatography

Besides its use in separating and quantitating sample components, affinity chromatography can also be employed as a tool for studying solute–ligand interactions. This application of affinity chromatography is called *analytical*, or *quantitative, affinity chromatography*. Using this technique, information can be acquired regarding the equilibrium and rate constants for biological interactions, as well as the number and types of binding sites that are involved in these interactions.[23,69]

Information on the equilibrium constants for a solute–ligand system can be obtained by using either the method

Figure 9 Injection of a mixture of ribonuclease A (1), transferrin (2), and carbonic anhydrase (3) onto an immobilized iminodiacetic acid column in (a) the presence of Zn^{2+} complexed to the column and (b) in the absence of Zn^{2+}. Chromatogr.*, **354**, 511–517, Copyright (1986), with permission from Elsevier Science.)

Figure 10 (a) Chromatograms and (b) relationship between the retention factor (k) and mobile phase additive concentration for zonal elution competitive binding experiments performed on an immobilized human serum albumin column using *R*-warfarin as the injected analyte and L-reverse triiodothyronine (L-rT_3) as a mobile phase additive. The mobile phase concentrations of L-rT_3 in (a) were (left-to-right) 1.90, 0.97, 0.49, 0.24 and 0 μM. (Reprinted from B. Loun, D.S. Hage, 'Characterization of Thyroxine–Albumin Binding Using High-performance Affinity Chromatography. II. Comparison of the Binding of Thyroxine, Triiodothyronine and Related Compounds at the Warfarin and Indole Sites of Human Serum Albumin', *J. Chromatogr. B*, **665**, 303–314, Copyright (1995), with permission from Elsevier Science.)

of *zonal elution* or *frontal analysis*. Zonal elution involves the injection of a small amount of solute onto an affinity column in the presence of a mobile phase that contains a known concentration of a competing agent. The equilibrium constants for binding of the ligand with the solute (and competing agent) can then be obtained by examining how the solute's retention changes with competing-agent concentration. A typical zonal elution experiment is shown in Figure 10. This technique was first used to study biological interactions by Andrews et al. in 1974[70] and by Dunn and Chaiken in 1975.[71] Since that time it has been used to examine a number of systems, such as enzyme–inhibitor binding, protein–protein interactions, and drug–protein binding.[5,10,23,69]

Frontal analysis is performed by continuously applying a known concentration of solute to an affinity column at a fixed flow-rate. The moles of analyte required to reach the mean point of the resulting breakthrough curve is then measured and used to determine the equilibrium constant for solute–ligand binding. This method was used first by Kasai and Ishii in 1975 to examine the interactions of trypsin with various peptide ligands.[72] It has since been used in many other applications.[23,69] One advantage of this approach over zonal elution is that it simultaneously provides information on both the equilibrium constants and the number of active sites involved in analyte–ligand binding. The main disadvantage of this method is the need for a larger quantity of solute then is required by zonal elution.

Information on the kinetics of solute–ligand interactions can also be obtained using affinity chromatography. A number of methods have been developed for this, including techniques based on band-broadening measurements,[73–77] the split-peak effect,[29,32,33] and peak decay analysis.[23] These methods are generally more difficult to perform than equilibrium constant measurements but represent a powerful means of examining the rates of biological interactions. Systems that have been studied by these techniques include the binding of lectins with sugars,[23,74,75] protein A or protein G with immunoglobulins,[29,33] antibodies with antigens,[23,32] and drugs or amino acids with human serum albumin.[76,77]

4.6 Miscellaneous Ligands and Methods

Besides the specific methods already discussed, a number of other ligands and techniques are often placed under the category of affinity chromatography. For example, boronic acid and its derivatives represent a class of general ligands that are usually considered to be affinity ligands. At a pH of 8 or higher, these ligands have the ability to form covalent bonds with compounds that contain cis-diol groups in their structure. This makes these ligands useful for the purification and analysis of many compounds which contain sugar residues, such as polysaccharides, glycoproteins, ribonucleic acids, and catechol-related compounds.[78–80]

Other methods that are related to affinity chromatography include *hydrophobic interaction chromatography* (*HIC*) and *thiophilic adsorption*. HIC is based on the interactions of proteins, peptides, and nucleic acids with short nonpolar chains on a support. This was first described in 1972[81,82] following work that examined the role of spacer arms on the nonspecific adsorption of affinity columns.[82] Thiophilic adsorption, also known as *covalent* or *chemisorption chromatography*, makes use of immobilized thiol groups for solute retention.[83] Applications of this method include the analysis of sulfhydryl-containing peptides or proteins and mercurated polynucleotides.[6]

5 FUTURE DEVELOPMENTS

A clear trend that has been present since the beginning of affinity chromatography has been the search for new and improved ligands to use in this technique. It has already been shown how a variety of biological and nonbiological compounds have been employed in affinity separations. In the future it is anticipated that an even greater variety of affinity stationary phases will be developed. One group of promising candidates are the aptamers, which are polymers of 8–120 nucleotides that have well-defined sequences and three-dimensional structures. It has been shown that a large number of aptamers can be randomly generated in an oligonucleotide library and then those ligands which bind to a given target solute can be selectively enriched for use in chemical sensors or other applications. The result is a ligand that is stable, easy to prepare and that has a relatively high affinity for the solute of interest.[84–86]

Another active area of new stationary phase development is in the field of molecular imprinting.[87,88] In this case, the affinity ligand is actually part of the surface or internal structure of the support used in the affinity column. Molecular imprints are usually made by combining the analyte of interest with a series of monomers that contain side chains capable of forming various interactions with the analyte. As these interactions take place, the monomers are fixed in position about the analyte by initiating their polymerization (see Figure 11). After the polymerization has occurred, the support is ground into a powder, the retained analyte is released by applying an appropriate solvent, and the imprinted support is placed into a column for use. In this way, an affinity support is created that has a known specificity and binding/elution properties.[87]

A second trend in affinity chromatography has been the increasing use of this method in tandem analytical techniques. For instance, Table 5 shows how IAC has already been combined, both on-line and off-line, with HPLC, GC and capillary electrophoresis.[11] Similar interfaces have been developed for other ligands (e.g. protein A, protein G, and boronic acid), but these have not seen nearly as much use as immunoaffinity columns in tandem techniques. One role that an affinity column can play in such a tandem system is to selectively extract an analyte or group of analytes from a sample prior to study by a second analytical method. The affinity column can also be used as a type of sensor to selectively monitor a given agent as it appears in the other analytical technique. The enhanced specificity that results in the overall method is a key reason why tandem affinity systems are receiving a good deal of attention in areas such as pharmaceutical analysis, food testing, and environmental monitoring.[11,28]

Biopolymers are biological macromolecules including peptides, proteins, nucleic acids, and polysaccharides whose physical and chemical properties differ considerably from those of small molecules. Biopolymer chromatography is a branch of liquid chromatography which is adapted to the specific requirements of biopolymers in order to obtain rapid and high-resolution chromatographic separations of these molecules. Because of the low diffusion coefficients of biopolymers, special stationary phase configurations and surface modifications are necessary to permit sufficiently fast mass transfer kinetics between the mobile and stationary phase. Exploiting different molecular properties of the biopolymers, such as size, charge, hydrophilicity, hydrophobicity, the ability to form complexes with metal ions, or biological function, the most popular liquid chromatographic modes for biopolymer separation are size-exclusion, ion-exchange, normal-phase, reversed-phase, ion-pair reversed-phase, metal-interaction, and affinity chromatography.

Because of their large size and the multitude of different functional groups present in biopolymers, more than one mechanism may be responsible for interaction with the stationary phase, resulting in enhanced selectivity due to mixed-mode interactions. Adsorption at multiple sites results in very steep elution isotherms as a function of the mobile phase solvent strength. Therefore, elution with a gradient of increasing solvent strength is usually applied in biopolymer chromatography. The choice of a suitable chromatographic environment is of special importance if

the native confirmation of a biopolymer, which is essential for its biological activity, is to be preserved for subsequent experiments. Generally, conditions that come close to the physiological environment are most appropriate.

The most important detection techniques for biopolymers are ultraviolet/visible absorbance detection, fluorescence detection, electrochemical detection, mass spectrometry, and low-angle laser light scattering photometry. Miniaturization and multidimensional separation together with mass spectrometric detection allow the routine separation and identification of femtomole–attomole amounts of hundreds to thousands of different biopolymers contained in complex mixtures of biological origin.

1 INTRODUCTION

Biopolymers are naturally occurring macromolecules, primarily peptides, proteins, nucleic acids, and polysaccharides, that represent essential constituents of all living organisms.[1] Their molecular mass ranges from roughly 1000 to several million. Although biopolymers exhibit an immense structural and functional diversity, they share a common building principle where relatively few building blocks of different chemical structure are assembled into polymeric chains that constitute the three-dimensional structure of the biomacromolecule. Thus, an estimated number of 10^{11} naturally occurring proteins is built up by only 20 amino acids and the whole human genome comprising 3×10^9 nucleotides contains only four different nucleobases. The characterization and structural analysis of biopolymers is of utmost importance in all areas of biological sciences and represents the key to understanding their biological function.

Biopolymers are usually present in relatively complex mixtures, hence separation before structural investigation is obligatory. The two principal and most powerful methods to asses the composition of biological samples and to separate the individual components are liquid chromatography (LC)[2] and electrophoresis.[3] The extraordinary popularity of high-performance liquid chromatography (HPLC) for the separation and analysis of biopolymers can be attributed to a number of factors:

1. Excellent resolution can be achieved for both closely related and structurally disparate substances under a large variety of chromatographic conditions.
2. Chromatographic selectivity can be manipulated readily through changes in mobile phase composition and/or choice of a suitable stationary phase from a large number of commercially available stationary phases.
3. Even submicrogram amounts of biopolymers can be isolated with high recovery.
4. Rapid separation and quantitation can be carried out with high reproducibility and accuracy on a timescale ranging from a few seconds to hours.

In principle, the theory of LC for biopolymers is the same as that for small molecules (see **Column Theory and Resolution in Liquid Chromatography**). However, as the diffusion coefficient decreases with increasing solute molecular mass, 1–2 orders of magnitude can separate the diffusion rates of small and large molecules in the liquid phase (e.g. diffusion coefficient of 9×10^{-6} versus $0.6 \times 10^{-6}\,cm^2\,s^{-1}$ for alanine and hemoglobin in water, respectively). The slow diffusion characteristics of biopolymers are responsible for slow kinetics of adsorption/desorption at the stationary phase and secondary equilibria resulting in lower column efficiency relative to separations involving small molecules. On the other hand, the separation selectivity for biopolymers is often better than for small molecules allowing the application of gradient elution, which counterbalances the lower column efficiency and has the additional advantage of increasing the peak capacity (see **Gradient Elution Chromatography**).

In many cases, especially for proteins, the three-dimensional structure of a biopolymer is essential for its biological activity. Therefore, careful choice of the appropriate method and chromatographic conditions is necessary to preserve the three-dimensional structure during the chromatographic separation process if the separated material is to be used for subsequent investigations where biological activity is important. Generally, chromatographic conditions similar to the physiological environment, such as aqueous buffer solutions at neutral pH, are most appropriate for the preservation of biological activity. However, biopolymers in solution can have parts of the molecule as well as the whole molecule folded, resulting in a variety of different conformations. If the time required for interconversion of these various more or less folded species is comparable to the time of separation, the resulting peak profiles are quite wide and often misshapen, resulting in poor separation efficiency. Therefore, strongly denaturing conditions, e.g. extreme pH, high temperature, or organic solvents, help to improve the resolving power of chromatography as a result of higher chromatographic selectivity for unfolded or partially denatured forms than for the native form of biopolymers at the cost of loss of biological activity.

2 SEPARATION PRINCIPLES FOR BIOPOLYMERS

There are a great number of chromatographic methods available for the fractionation of biopolymers that are designed to sense differences in size, shape, flexibility,

charge, polarity, or biological function of the compounds to be separated.[4] It has been appreciated that the so-called noninteractive modes of chromatographic separation do not exhibit the same level of resolution as the interactive modes.[2] Consequently, the most successful separation techniques are those capable of selective interaction by probing the topography of biopolymers.

Size-exclusion chromatography (SEC) and slalom chromatography represent exceptional modes in that the separation of the sample components takes place without their interaction with the stationary phase and, therefore, they are called noninteractive modes of chromatography (Table 1). By contrast, the interactive modes are conveniently identified by the term of the particular interaction (Table 1). Thus, we distinguish between electrostatic interaction, where immobilized charges on the stationary phase interact with the charged biopolymer molecules, polar interaction, where permanent or induced dipoles interact with each other, and hydrophobic interaction, where the interaction is between hydrophobic moieties. Since charged, polar, and hydrophobic domains are all present on the surface of most biopolymers, these interactions are of general type. In metal interaction chromatography (MIC), biopolymers are retained by the semispecific complexation of an immobilized metal ion at the stationary phase. Involving electrostatic, polar, and dispersive interactions as well as steric factors of interaction at the same time, affinity chromatography (AC) exploits highly specific interactions characteristic of many biochemical systems.

Table 1 Principal chromatographic modes for biopolymer separation

Chromatographic mode	Acronym	Separation principle
Noninteractive modes of liquid chromatography:		
Size-exclusion chromatography	SEC	Differences in molecular size
Slalom chromatography	–	Differences in length and flexibility
Interactive modes of liquid chromatography:		
Ion-exchange chromatography	IEC	Electrostatic interactions
Normal-phase chromatography	NPC	Polar interactions
Reversed-phase chromatography	RPC	Dispersive interactions
Ion-pair reversed-phase chromatography	IPRPC	Electrostatic interactions
Hydrophobic interaction chromatography	HIC	Dispersive interactions
Affinity chromatography	AC	Biospecific interaction
Metal interaction chromatography	MIC	Complexation with an immobilized metal

Macromolecular solutes interact with the stationary phase in a different way from that of small molecules. Because of the large molecular dimensions of biopolymers, it can be expected that the geometry and distribution of charged, hydrophobic, polar, and complexing groups on their surface greatly influence the adsorption behavior. Several of such adsorption sites on the biopolymer surface make it highly probable that adsorption at the stationary phase will occur at multiple sites.[5] This characteristic, unique to macromolecules, is responsible for extremely steep elution isotherms resulting in an enormously rapid change in solute retention with small changes in the elution strength of the mobile phase, a phenomenon often referred to as the 'on–off' model.[4] According to this model, the solute initially sticks at the inlet of the column and at some critical solvent strength during a gradient run it is totally desorbed and rapidly elutes from the column (Figure 1).

2.1 Size-exclusion and Slalom Chromatography

SEC separates biopolymers on the basis of their size and is different from the interactive modes of chromatography in that any interaction between the analytes and the stationary phase has to be prevented. The size-exclusion effect is based on the fact that the stationary phase particles have pores with a defined distribution of pore diameters. Large molecules of dimensions larger than

Figure 1 Plots of the logarithmic retention factor versus the concentration of acetonitrile in the RPC (reversed-phase chromatography) of lysozyme (M_r 16 951.5, solid lines) and nitrobenzene (M_r 123.11, dashed lines) on a PLRP-S macroporous, cross-linked polystyrene stationary phase from Polymer Laboratories. Methods Instrum.*, **1**, 213–222 (1993), Copyright John Wiley & Sons Limited. Reproduced with permission.)

Figure 2 Principles of (a) SEC and (b) slalom chromatography.

the pore diameter are totally excluded from the internal volume and leave the column first (Figure 2a). For small molecules, all pore diameters are large enough to allow penetration of the whole internal volume. Molecules of intermediate size have access only to a portion of the internal volume but will be excluded from the smaller pores. Thus, in SEC, analytes are separated by molecular size.

The upper molecular mass limit of SEC is determined by the maximum pore diameter of the packing material and the shape of the biomacromolecule. For instance, approximately 20% of the pore volume of a stationary phase with 10 nm average pore diameter is accessible for proteins with a molecular mass of 50 000 whereas 50% of the pore volume of a stationary phase with 50-nm pores is accessible for proteins with a molecular mass of around 500 000. The molecular size of linear polymers of random coil structure, such as nucleic acids or linear polysaccharides, is closely related to the molecular mass. Proteins, however, exist in an ordered tertiary structure, which is much denser than that of random coils. Consequently, they can penetrate more of the pore volume than random coiled biopolymers of commensurate molecular mass. In Table 2, the molecular masses and sizes of some biopolymers are summarized.

Table 2 Molecular masses and sizes of some biopolymers

Biopolymer	M_r	Molecular dimensions (nm)
Cytochrome *c*	12 310	$2.5 \times 2.4 \times 3.7$[a]
Carbonic anhydrase	28 800	$4.7 \times 4.1 \times 4.1$[a]
Lactate dehydrogenase	146 200	$7.4 \times 7.4 \times 8.4$[a]
Ferritin	474 000	$8 \times 8 \times 8$[a]
DNA, 100 base pairs	69 400	$35 \times 2 \times 2$ (straight rod)
DNA, 800 base pairs	519 200	$60 \times 60 \times 60$ (random coil)[b]

[a] Determined from crystal structure.
[b] Calculated by the Kratky–Porod relation.[6]

Slalom chromatography has been developed for the separation of large, double-stranded DNA molecules (>1000 base pairs) that behave like a flexible random coil in aqueous solution.[7] When DNA molecules are applied to a column which is packed with hard and spherical beads, they are unfolded and extended owing to the laminar flow of solvent passing through the narrow openings between the closely packed particles. The separation is based on the fact that long DNA molecules (5000–50 000 base pairs) have to turn very fast during their passage through the narrow and tortuous channels between the packing particles (Figure 2b). The longer the DNA molecule, the more difficult it is to pass through the openings and, consequently, a separation according to size, where smaller DNA molecules elute first, is achieved. Important features of slalom chromatography are that DNA fragments do not interact with the column packing, that separation depends strongly on particle size and flow rate, and that the DNA fragments are totally excluded from the pores, and therefore pore size and pore volume are not important factors in determining the separation.

2.2 Ion-exchange Chromatography

Ion-exchange chromatography (IEC) separates molecules based on differences in their accessible surface charges (see **Ion Chromatography**). An ion-exchange stationary phase consists of positively charged (for anion exchange, see Figure 3a) or negatively charged (for cation exchange) functional groups immobilized on a suitable support material. The electrostatic interactions between the oppositely charged groups on the surface of the stationary phase and on the surface of the analytes are responsible for adsorption. Since biopolymers also contain nonpolar areas, relatively weak dispersive interactions with the stationary phase may provide additional retention.

Desorption takes place when the ionic strength of the mobile phase is increased by applying a gradient of increasing salt concentration. The salt concentration needed to displace the adsorbed biopolymers back into the mobile phase depends on the strength of the

Figure 3 Principles of (a) IEC and (b) RPC. Shaded areas represent hydrophobic regions of the protein.

electrostatic interactions between the stationary phase and the biopolymer.

Consequently, the retention behavior of biopolymers in IEC depends strongly on their charge characteristics. The total net charge and the actual distribution of charges within a biomacromolecule critically affect both adsorption and elution. Whereas the phosphodiester groups of nucleic acids are dissociated over a broad pH range (2–14), the pH of the mobile phase strongly influences the charge characteristics of peptides and proteins. Oligosaccharides can be ionized only at pH values higher than 12 owing to the weak acidity of the hydroxyl groups. In addition to affecting the charge distribution within the molecule, the pH can also have an effect on the three-dimensional conformation of a biomacromolecule. Because of these phenomena, the effect of pH on the chromatographic selectivity can be profound and difficult to predict and an empirical approach to evaluate an ion-exchange separation over a range of pH values is necessary. The advantage of the ion-exchange mechanism is that under suitable pH conditions, relatively few or no structural changes in the biopolymers occur because the interaction between the stationary phase and the analyte is weak apart from the electrostatic interactions which are directed and specific.

2.3 Normal-phase Chromatography

In normal-phase chromatography (NPC), the stationary phase is more polar than the mobile phase (see **Normal-phase Liquid Chromatography**). The intermolecular interactions governing retention and selectivity in this mode are polar in origin, encompassing both hydrogen bonding, the extent of which depends upon the Lewis acidity or basicity of the interacting molecules, and dipole–dipole interaction, which is dependent on the dipole moments and polarizabilities of the molecules. The polar surface of a normal-phase stationary phase can either be obtained by derivatizing a support material with a suitable polar functional group, or it can be the original support, as in the case of silica gel. The retention of polar analytes increases with increasing hydrophilicity of the stationary phase and with decreasing hydrophilicity of the mobile phase, typically mixtures of organic solvents.

2.4 Reversed-phase Chromatography

Reversed-phase chromatography (RPC) separates biopolymers on the basis of differences in their hydrophobic properties (see **Reversed Phase Liquid Chromatography**). The stationary phase in RPC is a very hydrophobic, nonpolar surface, whereas the mobile phase is polar, usually a mixture of water and organic solvents. The hydrophobic interaction results from a tendency of nonpolar molecules to interact with each other rather than with water, resulting in the distribution of a hydrophobic solute between the hydrophobic hydrocarbon chains of the stationary phase and the mobile phase (Figure 3b). Reducing the polarity of the mobile phase through increasing the concentration of an organic solvent allows the hydrophobically bound analytes to desorb from the stationary phase, causing elution from a reversed-phase column. Under the conditions of RPC, i.e. the employment of hydroorganic solvents in combination with a strongly hydrophobic surface, proteins often lose their three-dimensional shape and denature, resulting in loss of biological activity, which cannot always be restored by putting the protein in a more physiological environment after separation. Nevertheless, the high resolution capability of this technique is a result of higher chromatographic selectivity for unfolded or partially denatured forms than for the native forms of the proteins, which makes RPC an important tool for high-resolution analytical separations.

2.5 Ion-pair Reversed-phase Chromatography

Ion-pair reversed-phase chromatography (IPRPC) is traditionally seen as a special branch of RPC because stationary phases and elution conditions typical for RPC are used. However, from a mechanistic point of

Figure 4 Principles of (a) IPRPC and (b) HIC. Shaded areas represent hydrophobic regions of the protein.

view, it is rather a branch of IEC because retention is governed by electrostatic interactions. In IPRPC, the phase system comprises a hydrophobic stationary phase and a hydroorganic eluent containing an amphiphilic ion that carries both charged and hydrophobic moieties. According to the electrostatic retention model,[8] the positively or negatively charged amphiphilic ions are adsorbed at the interface between the nonpolar stationary phase and the hydroorganic mobile phase, resulting in a surface potential that electrostatically interacts with solute molecules of opposite charge (Figure 4a). Elution of bound molecules is accomplished by increasing the concentration of an organic modifier, resulting in a decrease in surface potential because of desorption of amphiphilic ions from the stationary phase. Additional hydrophobic interactions between hydrophobic solutes and the hydrophobic surface of the stationary phase are possible in IPRPC.

2.6 Hydrophobic Interaction Chromatography

Hydrophobic interaction chromatography (HIC) separates biopolymers based on the hydrophobicity of their surface. Binding of biopolymers is induced by the addition of high salt concentration ($1–5\,\text{mol}\,\text{L}^{-1}$) whereas elution is accomplished by lowering the salt concentration (Figure 4b). The organization of the water molecules surrounding the analytes and the binding surface is the driving force for hydrophobic adsorption. When a hydrophobic region of a biopolymer binds to the surface of a mildly hydrophobic stationary phase, hydrophilic water molecules are effectively released from surrounding the hydrophobic areas, causing a thermodynamically favorable change in entropy. Because hydrophobic interaction is driven by entropy, temperature can have a strong effect.

Compared with RPC, the surface of the stationary phase in HIC is less hydrophobic so that no organic solvent is necessary for desorption of the analytes. Therefore, the three-dimensional structure of biopolymers is usually preserved during a separation by HIC. Ammonium sulfate, by virtue of its good salting-out properties and high solubility in water, is the most common salt used for HIC. The salt concentration required for the induced hydrophobic interaction can be modulated by changing the hydrophobicity of the stationary phase. More hydrophobic phases require less salt for binding. If the bonded phase is too apolar, the analytes do not elute when the salt is removed.

2.7 Affinity Chromatography

AC is based on biospecific interactions between a ligand covalently bound to the chromatographic packing and a target biopolymer in the sample solution (see **Affinity Chromatography**). The technique is almost exclusively utilized to purify proteins, although there are a few applications with peptides and nucleic acids. The forces involved in biospecific interaction include the same electrostatic and hydrophobic interactions that cause more nonspecific ion-exchange and hydrophobic binding. However, in the case of biospecific or affinity binding, the interacting groups are arranged on the two bonding molecules in a unique orientation. Moreover, hydrogen bonding also plays an important role. The two ligands thus fit together very much like a lock and key, with a high degree of specificity (Figure 5a). Elution from affinity media can be done under any conditions that disrupt the ligand–ligand interaction. The most common technique is to employ a shift to acidic pH (2–4), which induces dissociation because of protonation of acidic groups. Other elution techniques include the increase of ionic strength or the use of specific displacers such as the immobilized ligand or an analog in free solution. Affinity elution is usually in the form of a step gradient.

2.8 Metal Interaction Chromatography

MIC is a method for the separation of biopolymers which are capable of complexing with an immobilized

Figure 5 Principles of (a) AC and (b) MIC.

transition metal ion on the surface of a suitable support. The metal ion (typically Cu^{2+}, Zn^{2+}, Ni^{2+}, Co^{2+}, or Fe^{3+}) is usually bound to the support by means of a chelating ligand (typically iminodiacetate) such that one or more coordination sites are available for interaction with ligands that are part of biopolymers (Figure 5b). Typical functional groups in biopolymers capable of complexation with transition metal ions are imidazole, amino, and thiol groups present in the amino acids histidine, lysine, and cysteine (with Cu^{2+}, Ni^{2+}), phosphate groups in nucleic acids (with Fe^{3+}), and vicinal diols present in saccharides (with Cu^{2+}). Elution of complexed biopolymers is accomplished with gradients of increasing salt concentration or, even more effective, with increasing gradients of competitive ligands such as imidazole or phosphate.

3 STATIONARY PHASES FOR BIOPOLYMER SEPARATION

The choice of a suitable stationary phase is one of the first decisions to be made in the design of a chromatographic separation for a biopolymer mixture. Initially, it was assumed that the pool of packing materials commercialized for the separation of low molecular mass analytes could be easily transferred to the separation of biopolymers.[9] However, it soon became apparent that the handling of these substances in HPLC requires careful control of the morphology and the surface chemistry of the chromatographic packing material. The two major concerns that have to be taken into account with biopolymers are slow mass transfer because of the low diffusivities of biopolymers and multimodal interaction of biopolymers with the stationary phase. Usually it is advantageous to restrict the molecular interactions between analyte molecules and the stationary phase to one predominant interaction (single-mode interaction, Table 1), although other forces and mechanisms may play a role in determining the final separation (mixed-mode or multimode interaction). In many cases, however, these additional interactions are difficult to control and result in band broadening and asymmetric peak shapes.

For size-exclusion packing materials, the pore size distribution and a surface chemistry that prevents any interaction between the stationary phase and the analyte are the factors determining the success of separation. In the interactive modes of chromatography the driving forces of retention and selectivity are the molecular interactions between the analyte and the surface of the stationary phase. Additionally, the steric environment of the packing materials affects the molecular interactions. The selection of an optimal pore size for a particular sorbent is made on the basis that the solute molecular diameter (Table 2) must be a least one-tenth the size of the pore diameter of the packing material to avoid restricted diffusion of the solute and to allow the total surface of the sorbent material to be accessible. Therefore, compared with packings for separating small molecules, larger pore sizes of 15–100 nm or nonporous packing materials are needed for biopolymers.

3.1 Stationary Phase Support Materials and Functional Groups

Modern support materials used in HPLC are either derived from inorganic or organic polymers or are composites of these types. Inorganic supports comprise hydrous oxides (silica, alumina), phosphates (hydroxyapatite), silicates, porous glasses, and carbon materials. Usually, inorganic supports are hydrophilic (except for carbon, e.g. porous graphitic carbon) and possess acidic and/or basic functional groups. Cross-linked organic polymers exhibit a wide range of polarity, depending on the polymer backbone and the functional groups. The most prominent organic polymers include polyamide, polybutadiene, polysaccharides, polymethacrylates, poly(vinyl alcohol), and styrene–divinylbenzene copolymers. Silica-based packing materials are used in about 75% and

Table 3 Functionalities needed for different modes of chromatography

Chromatographic mode	Functional group	Remarks
SEC	Surface functionality is chosen such that no molecular interactions occur	Selectivity is provided by the pore-size distribution of the packing
Slalom	Surface functionality is chosen such that no molecular interactions occur	Selectivity is provided by the particle diameter of the packing combined with the flow rate
IEC	Sulfonic acid, carboxylic acid	For cation exchange
	Primary, secondary, tertiary, or quaternized amino groups	For anion exchange
NPC	–	Underivatized silica gel
	Hydroxyl-, diol-, amino-, cyano groups	Bound to silica gel or polymeric supports
RPC and IPRPC	–	Underivatized nonpolar polymers, e.g. PS/DVB
	Butyl, phenyl, octyl, or octadecyl groups	Bound to silica gel or polymeric supports
HIC	Methyl, butyl, or phenyl groups	–
AC	Epoxy, aldehyde, or aryl ester groups	Preactivated packings are commercially available; the specific affinity ligand is usually attached by the user
MIC	Iminodiacetate groups with complexed transition metals	Metals complexed: Ni(II), Co(II), Cu(II), Zn(II), Fe(III)

polymers in about 20% of all separations performed today.[10]

Silica gel is available with irregular- and spherical-shaped particles and with a wide variety of particle diameters, pore diameters, and pore volumes. Moreover, silica-based stationary phases are mechanically stable, provide excellent efficiency, and can be converted to bonded-phase materials by virtue of their reactive silanol groups (see **Silica Gel and its Derivatization for Liquid Chromatography**). However, silica has some limitations: it dissolves rapidly at pH > 9 and the acidic silanol groups cause tailing or irreversible adsorption of basic compounds.

The most popular polymeric support is polystyrene cross-linked with divinylbenzene [poly(styrene/divinylbenzene) (PS/DVB)]. Depending on the degree of cross-linking and the amount of porogen used in their production, polymeric packings are also available with a variety of particle diameters, porosities, and mechanical strengths. Polymeric packings are generally stable over a wider pH range than silica gel, and some can operate throughout the full pH 0–14 range. Polymers do not exhibit silanol activity, however hydrophobic or charged entities of the polymer backbone can be a source of additional interactions resulting in multimode adsorption.

Both types of support materials, inorganic oxides or organic polymers, can be surface functionalized by well-established methods[11,12] to obtain suitable stationary phases for the various chromatographic modes. Table 3 summarizes some of the most commonly used functionalities for the different modes of biopolymer chromatography.

A tremendous number of packing materials for different modes of chromatography are commercially available, and the market constantly changes with the introduction of new materials. Therefore, for the selection of a column for specific applications the reader is referred to comprehensive tables in recent monographs[13,14] or periodical reviews appearing in analytical journals.[10,15,16]

3.2 Stationary Phase Morphologies with Enhanced Mass Transfer Properties

Since slow mass transfer kinetics is often the limiting factor for speed and efficiency in biopolymer separations, the enhancement of intraparticular mass transport is particularly important for the rapid separation of large molecules having low diffusivities.[17,18] The different routes to enhance the mass transfer of biopolymers in stationary phases include (1) increasing the pore diameter and decreasing the particle diameter, (2) eliminating the support pores by using nonporous stationary phases, (3) decreasing the pore depth by using superficially porous stationary phases, (4) introducing pores of 600–800 nm diameter transversing the particle that cause the liquid to flow through the particle, and

Figure 6 Schematic illustration of stationary phase configurations with enhanced mass transfer properties. (a) Macroporous packing; (b) nonporous packing; (c) bidisperse packing with macropores and gigapores; and (d) continuous chromatographic bed.

(5) using porous, continuous-bed polymers as the chromatographic bed.

The first attempts to adapt stationary phases for biopolymer separations applied small particles with large pores (macroporous particles)[9] that yield enhanced column efficiency by virtue of the relatively small intraparticular mass transfer resistance due to the short diffusion distances (Figure 6a). Another way to circumvent intraparticle diffusion is the complete elimination of the support pores.[19,20] Through the use of nonporous particles that lack any intraparticular pores, the only remaining particle-based diffusion limitations are in a thin layer of stagnant liquid at the surface of the particle (Figure 6b). The only limitation of nonporous sorbents is that they have approximately 1% of the surface area of porous sorbents and are, therefore, of limited loading capacity for preparative separations. This problem has been addressed by attaching a 1-μm thick layer of porous particles to the exterior surface of nonporous particles.[21] These poreshell particles with a total diameter of around 5 μm have pores of 1 μm depth or less and a loading capacity around 65% of that of a totally porous particle.

Another approach to the problem of stagnant mobile phase mass transfer is to cause the liquid to flow (or perfuse) through the particles. Introduction of 600–800-nm pores transversing the particle allows a small portion of the mobile phase to perfuse the porous support.[22] The surface area of perfusion chromatography supports is increased by a network of smaller, 50–150-nm pores of 1 μm or less in depth that interconnect the large throughpores (Figure 6c). Finally, the concept of continuous chromatographic beds, where the separation medium consists of a continuous rod of a rigid, macroporous polymer which has only internal porosity consisting of macropores and gigapores, has been developed to alleviate the problem of mass transfer (Figure 6d).[23,24] Because of the absence of intraparticular volume, all of the mobile phase is forced through the large pores in the separation medium, resulting in enhanced mass transport by convection.

4 BIOPOLYMER DETECTION

In this section, the aspects of detection important for biopolymers are emphasized.[14] There is no one single ideal detector for biopolymers, hence the chromatographer is forced to utilize several detection systems that all sense different molecular properties of the solute to be detected such as absorption of electromagnetic radiation, fluorescence, electrochemical activity, and molecular mass. The usual detector requirements also prevail for HPLC of high molecular mass biopolymers and include high linear dynamic range, high sensitivity, low limit of detection, low detector noise level, baseline stability, high signal-to-noise ratio, fast time constant, low peak dispersion, and the ability to quantitate with good detectability, reproducibility, and accuracy.[25] Moreover, an ideal detector system for biopolymer chromatography should be nondiscriminating in the sense of being able to detect with low limits of detection the variety of different compounds that are present in complex mixtures of biological origin. From another point of view, detection systems should yield information about the identity and structure of the detected biopolymer to permit the differentiation between biopolymers even of very similar structure. Another ideal property of a biopolymer detector is nondestruction, that is, the ability of samples to be recovered after detection to be used for subsequent analyses or biological testing. The most commonly used detection methods for biopolymers are ultraviolet/visible (UV/VIS) absorbance detection, fluorescence (FL) detection, electrochemical detection (ELCD), mass spectrometry (MS), and low-angle laser light scattering (LALLS) photometry. Although suffering from high limits of detection, refractive index detection is one of the few options for universal detection in LC and has to be used for biopolymers that lack any chromophore, fluorophore, or electroactive group.

4.1 Ultraviolet/Visible Absorbance and Fluorescence Detection

Spectrophotometric techniques are among the most widely applicable for the detection of biopolymers. The absorbance maximum for the peptide bond is around 185 nm, but most eluents used for chromatographic separations absorb light strongly below 200 nm. Therefore, peptides and proteins are usually detected at wavelengths between 210 and 220 nm. Nevertheless, a host of other ultraviolet (UV)-absorbing compounds present in biological samples may cause interferences with separation and quantitation. In this situation, alternative wavelengths that can be monitored include the regions of absorbance of the side chains of tryptophan and tyrosine (280 nm) or, less commonly, phenylalanine (254 nm), cystine (240 nm), or histidine (228 nm). Proteins containing prosthetic groups, such as metalloproteins, often may be selectively detected in the far-UV or visible (VIS) region, the wavelength being dependent on the oxidation state of the metal. Cytochrome *c* oxidase may be detected near 410 nm, whereas myoglobin absorbs at 405 nm, cytochromes at 550–560 nm, and hemoglobin at 415 nm.[26]

Nucleotides, the monomer units of nucleic acids, are UV active over the range 180–300 nm, with maxima at 180–200 and 250–280 nm. For the same reasons as described above for peptides and proteins, nucleic acids are normally detected at wavelengths between 250 and 260 nm. Polysaccharides are not ideal UV/VIS absorbers because of the absence of effective chromophores absorbing above 200 nm. Thus, underivatized polysaccharides have poor UV absorbance detection limits and other detection methods such as UV/VIS or FL detection after chemical derivatization or ELCD have to be used.

FL detection generally has very low limits of detection (10–1000 times lower than UV/VIS detection) but, as only a few percent of all compounds exhibit native FL, the method is highly selective. Non-fluorescing compounds can be tagged with fluorescent dyes by pre- or postcolumn derivatization. The native FL of tryptophan and tyrosine can be used for peptide and protein detection. By exciting at 220 nm and monitoring at 330 nm, tryptophan-containing peptides are detected with six times lower detection limits compared with UV absorbance detection. Native nucleic acids and polysaccharides usually do not contain any fluorophore so that FL detection of these compounds is possible only after derivatization with an appropriate fluorescent label (see section 4.4).

4.2 Electrochemical Detection

In all forms of ELCD the analytes are detected by the current generated at a working electrode by oxidation or reduction. The direct electrochemistry of biopolymers on noble metal electrodes frequently suffers from electrode fouling due to adsorption of oxidized species at the electrode surface. This problem has been addressed by the application of pulsed ELCD, where the electrode undergoes oxidative cleaning followed by reductive regeneration of the electrode surface through the application of a triple-pulse waveform. If the current is measured only at a specific voltage during the pulse, the technique is known as pulsed amperometric detection (PAD).

Amino acids that respond to ELCD include tyrosine, tryptophan, methionine, and cysteine/cystine with the electroactive groups phenol, indole, thioether, thiol, and disulfide, respectively. ELCD is, therefore, mainly used for selective determination of peptides containing such amino acids. A more general strategy for the ELCD of peptides is taking advantage of complexation reactions between copper(II) and amino acids at a copper electrode.[27] However, using ELCD for a wide range of peptides cannot currently be considered a general approach, since many peptides will not be detected.

Diffusion and proper orientation of the analyte to be oxidized or reduced at the electrode surface is of great importance in ELCD. The general use of ELCD for proteins is restricted by these two requirements, since proteins possess low diffusion coefficients and the electroactive groups may be buried inside the folded protein structure. Hence ELCD is restricted to certain specific proteins having special functionalities, e.g. heme groups,[28] accessible disulfide bridges,[29] or copper.[30]

Electrochemical oxidation of the purine bases at a carbon electrode can be used to determine nucleic acids.[31] The guanine and adenine bases can be readily distinguished owing to their different oxidation potentials (800 mV for guanine, 1080 mV for adenine versus Ag/AgCl). Nevertheless, like proteins, high molecular mass nucleic acids possess low diffusion coefficients, which eventually lead to poor sensitivity for larger nucleic acids.

PAD is the method of choice for detection of oligo- and polysaccharides with high sensitivity.[32] Aldehyde and terminal alcohol moieties in oligosaccharides can be oxidized at gold electrodes in alkaline media. A typical triple-pulse waveform for detection of oligosaccharides involves anodic oxidation of the analytes at a potential of 50–200 mV for 200–400 ms, oxidative cleaning of the electrode surface at 600–800 mV for 120–180 ms, and reduction of the electrode surface at −300 to 800 mV for 300–360 ms (Figure 7, all potentials versus Ag/AgCl).

4.3 Radioactivity Detection

Because of its very low detection limits, radioactivity (RA) detection of biopolymers is primarily applied in

Figure 7 Pulsed waveform for ELCD of saccharides.

studies involving very small amounts of sample in complex matrices. As the natural RA of the elements contained in biopolymers is extremely low, chemical or enzymatic labeling with radioelements of high specific activity is obligatory. Radioisotopes emitting β-radiation such as ^{3}H, ^{14}C, ^{32}P, or ^{35}S are the most commonly used radioactive labels. Examples of radioactive labeling reactions are given in Table 4.

4.4 Pre- and Postcolumn Derivatization

A chemical derivatization reaction allows the conversion of biopolymers with poor UV/VIS absorptivity or electrochemical activity into derivatives that can be detected with higher sensitivity. Moreover, chemical derivatization often enhances the selectivity when only certain functional groups characteristic of a biopolymer react during the derivatization procedure. Derivatizations can be performed before (precolumn) and after (postcolumn) a chromatographic separation. Postcolumn techniques allow the detection of biopolymers after separation in their native state, whereas precolumn derivatization changes both detection and chromatographic behavior. Tagging of biopolymers with FL labels is the method of

Table 4 Derivatization reagents for UV/VIS, FL, ELCD, and RA detection of biopolymers

Reagent	Used for	Derivatization	Detection[a]	Refs.
o-Phthaldialdehyde	Peptides	Precolumn, postcolumn	FL, Ex 340 nm/Em 400 nm	33
Fluorescamine	Peptides, proteins	Precolumn, postcolumn	FL, Ex 390 nm/Em 490 nm	34
Indocyanine green	Proteins	Precolumn	FL, Ex 765 nm/Em 820–840 nm	35
[^{14}C]Acetic anhydride or [^{3}H]acetic anhydride	Proteins	Precolumn	RA, β^- 0.156 MeV RA, β^- 0.018 MeV	36
[γ-^{32}P]ATP/protein kinase	Peptides and proteins containing threonine or tyrosine	Precolumn	RA, β^- 1.71 MeV	37
Fluorescein	Nucleic acids	Precolumn	FL, Ex 450 nm/Em 520 nm	38
Phenylglyoxal	Nucleic acids containing guanosine	Postcolumn	FL, Ex 365 nm/Em 515 nm	39
Chloroacetaldehyde	Nucleic acids containing adenosine	Postcolumn	FL, Ex 254 nm/Em 400 nm	40
[γ-^{32}P]ATP/polynucleotide kinase	Nucleic acids	Precolumn	RA, β^- 1.71 MeV	41
Thymol	Reducing and nonreducing polysaccharides	Postcolumn	VIS, 500 nm	42
1-Phenyl-3-methyl-5-pyrazolone	Reducing polysaccharides	Precolumn	UV, 245 nm	43
2-Aminopyridine	Reducing saccharides	Precolumn	UV, 290 nm FL, Ex 320 nm/Em 400 nm	44
2-Cyanoacetamide	Reducing saccharides with a β-hydroxyl group	Postcolumn	UV, 270, 330 nm FL, Ex 331 nm/Em 383 nm ELCD	45, 46
Sodium [^{3}H]borohydride	Polysaccharides	Precolumn	RA, β^- 0.018 MeV	47

[a] Em, emission wavelength; Ex, excitation wavelength.

choice for derivatization because of the high sensitivity of FL detection (approximately 1000 times more sensitive than UV/VIS detection). Whereas FL derivatization of peptides, proteins and nucleic acids is necessary only when UV absorbance detection of the native compounds is not sensitive enough, derivatization of polysaccharides is very common owing to the lack of chromophoric or fluorogenic groups. Table 4 lists some examples of derivatization reagents used for UV/VIS, FL, ELCD, and RA detection of peptides, proteins, nucleic acids, and polysaccharides.

4.5 Mass Spectrometry

The molecular mass of a biopolymer is a very important parameter for its characterization and identification. Because most biopolymers are very polar and nonvolatile molecules, the classical MS methods such as electron ionization (EI) MS or chemical ionization (CI) MS are not applicable. However, the development of new, soft ionization techniques, such as fast atom bombardment (FAB),[48] electrospray ionization (ESI),[49] and matrix-assisted laser desorption/ionization (MALDI)[50] has made MS applicable as an LC detection system for biopolymers (see **Atmospheric Pressure Ionization Mass Spectrometry**).

While FAB ionization is confined to small biopolymers up to molecular mass (M_r) 15 000,[51] ESI enables the transfer of proteins larger than M_r 130 000[52] and of nucleic acids larger than M_r 7 000 000[53] into the gas phase for mass analysis (Table 5). Moreover, electrospray ionization mass spectrometry (ESIMS) greatly benefits from the multiple charging of biopolymers resulting in mass-to-charge ratios well within the mass range of most commercial mass spectrometers ($\leq$4000–6000 u) even for very large biomolecules. By virtue of its versatility for ionization of various biopolymers, broad mass range, high mass precision (typically 0.01%), and tolerance for high eluent flow rates, the ESI interface is the most commonly used to couple LC and MS. MALDI/MS is frequently applied to the off-line analysis of collected fractions after chromatographic separation, although prototypes of continuous-flow MALDI interfaces have been reported.[54]

4.6 Light-scattering Detection

A general property of macromolecular species is that they scatter light. The light intensity scattered by a biopolymer in solution at a certain angle of incidence depends on the molecular mass and concentration of the solute in the detector cell. LALLS detectors are capable of providing unique information about the molecular mass, radius of gyration, and diffusion coefficient of biopolymers in solution. To evaluate the molecular mass term, the LALLS detector is coupled in series to a concentration-dependent detector, such as the refractive index detector, and the response from both detectors is used to calculate the molecular mass without the need for external calibration standards.[55] LALLS detection is very useful for the characterization of biopolymer aggregates formed in solution,[56] information that cannot be accessed by MS.

5 INSTRUMENTAL REQUIREMENTS FOR CHROMATOGRAPHIC BIOPOLYMER SEPARATIONS

In principle, any liquid chromatograph can be used for biopolymer separations. All that is needed is a mobile phase delivery system, a sample injector, a separation column, a column thermostat, a detector (most commonly a UV absorbance detector), and a data system. Because the retentive properties of the individual components in a mixture of biopolymers can be very different, gradient elution capability is needed in most of the separation problems. The leaking of metal ions from the stainless-steel construction of the various parts of a conventional chromatograph may be a source of problems because many biopolymers interact with metal ions, resulting in irreversible adsorption or loss of biological activity of the analytes. Moreover, stainless steel rapidly corrodes with eluents containing halide salts such as those applied in IEC. To prevent this occurrence, all wetted parts of the so-called ''biocompatible'' liquid chromatographs are fabricated from inert materials such as titanium, glass, poly(tetrafluoroethylene) (PTFE), or poly(ether ether ketone) (PEEK).

Table 5 MS detection methods for biopolymers

Ionization technique	Mass range for proteins	Mass range for nucleic acids	Flow rate range ($\mu L\,min^{-1}$)
ESI	Up to M_r 150 000	Up to M_r 7 000 000	0.01–1000
CFFAB[a]	Up to M_r 15 000	Up to M_r 5000	0.5–10
MALDI	Up to M_r 400 000	Up to M_r 800 000	Off-line detection

[a] CFFAB, continuous-flow fast atom bombardment.

6 SEPARATION OF PEPTIDES AND PROTEINS

The distinction between a peptide and a protein is somewhat arbitrary, with peptides usually being defined as molecules containing 50 amino acids or less. Molecules with >50 amino acids usually have a stable three-dimensional structure in aqueous solution and are referred to as proteins. Secondary structures such as α-helix or β-sheet are generally absent for small peptides up to approximately 15 residues. However, the potential for defined secondary, tertiary, and quaternary structure increases with increasing chain length. Moreover, folding to internalize hydrophobic residues to stabilize the protein structure in aqueous solution is likely to become a significant conformational feature. This potential to form a variety of structures results in a large diversity of naturally occurring proteins and poses great challenges to separation techniques in terms of selectivity and resolution.

6.1 Size-exclusion Chromatography

SEC is frequently used as a first step in a purification scheme to separate the molecules of interest from those which have radically different size characteristics. It can also be used to change the buffer environment or for the desalting of a biopolymer sample. Finally, SEC can be implemented as a means of determining molecular parameters such as average molecular mass and hydrodynamic radius. Figure 8(a) illustrates a typical separation of proteins by SEC. The stationary phase used for this separation is SynChropak GPC 300, a controlled-porosity silica support having an average pore diameter of 30 nm with a glycerylpropylsilane bonded phase to prevent adsorptive protein retention.[57] High molecular mass calf thymus DNA, which is completely excluded from the pores, is used as a marker for the void volume (V_0) whereas the small dipeptide glycyltyrosine can penetrate the total pore volume and serves as a noninteractive marker for the total volume (V_t). Solutes with a molecular size between the two extremes are eluted at a volume (V_e) which is between V_0 and V_t. The distribution coefficient K_d specifies the fraction of V_t available to a molecule according to the relationship $V_e = V_0 + K_d V_t$. Under ideal size-exclusion conditions, the logarithm of the molecular mass is a linear function of the distribution coefficient and this relation can be used to define a calibration graph for protein molecular masses as a function of the elution volume (Figure 8b).

6.2 Ion-exchange Chromatography

Although RPC is the most commonly used chromatographic mode for the separation of peptides, IEC

Figure 8 (a) SEC separation of proteins and (b) calibration graph for molecular mass determination of proteins. Column, SynChropak GPC 300 from Synchrom, 5 µm particle size, 30 nm pore size, 300 × 7.8 mm i.d.; mobile phase, 0.1 M potassium phosphate, pH 7.0; flow rate, 1 mL min^{-1}. Peak identification: 1, calf thymus DNA; 2, thyroglobulin; 3, β-amylase, 4, ovalbumin; 5, carbonic anhydrase; 6, glycyltyrosine. (Reprinted with permission from C.T. Mant, R.S. Hodges, *High-performance Liquid Chromatography of Peptides and Proteins*, CRC Press, Boca Raton, FL, 1991, Copyright Lewis Publishers, an imprint of CRC Press, Boca Raton, FL.)

represents the most promising alternative if RPC fails to separate the components of interest. At a pH near neutrality, anion-exchange chromatography is used for acidic peptides[58] and cation-exchange chromatography for basic peptides.[59] However, cation-exchange chromatography becomes applicable to peptides in general if a pH in the range 2.8–3.0 is employed, where peptide retention will be governed by the basic residues of lysine, arginine, and histidine, and the N-terminus. Figure 9 demonstrates that peptides are eluted with a gradient of increasing salt concentration in order of increasing absolute number of positively charged residues. The ability of anion-exchange chromatography to resolve peptides of the same net charge is attributable to some sort of

Figure 9 Separation of peptide standards by cation-exchange chromatography. Column, poly(2-sulfoethylaspartamide)silica, 5 μm particle size, 30 nm pore size, 200 × 4.6 mm i.d.; mobile phase, (A) 5 mM potassium phosphate, pH 3.0–25% acetonitrile, (B) 0.25 M potassium chloride in (A); linear gradient, 0–100% B in 40 min; flow rate, 0.7 mL min^{-1}. Peak identification: 1, oxytocin (1+); 2, [Arg^8]-vasopressin (2+); 3, somatostatin (3+), 4, substance P, free acid (3+); 5, substance P (3+); 6, bovine pancreatic polypeptide (5+), 7, anglerfish peptide (6+); 8, human neuropeptide Y (7+) (numbers in parentheses are net charge of the peptides at pH 3.0). Regnier, 'Flow-through Particles for the High-performance Liquid Chromatographic Separation of Biomolecules: Perfusion Chromatography', *J. Chromatogr.*, **519**, 1–29 (1990), Copyright 1990, with permission from Elsevier Science.)

mixed-mode interaction and/or to differences in the secondary structure of the peptides.

IEC is the method of choice for high-resolution separation of proteins in their native form without disrupting the three-dimensional structure. Figure 10 depicts the resolution of four standard proteins by anion-exchange chromatography on a stationary phase of the bimodal pore-size configuration (compare Figure 6c). A gradient of 0–0.35 M sodium chloride is applied to elute the proteins rapidly. The splitting of three of the four protein peaks into several incompletely resolved peaks and shoulders indicates the ability of IEC to distinguish between different isoforms of proteins, i.e. proteins of the same biological function but slightly different structure. The heterogeneity of ovalbumin (peak 3 in Figure 10), for instance, an M_r 43 000 glycophosphoroprotein consisting of 385 amino acids, is caused by oligosaccharides linked to asparagine 293 and two phosphorylation sites at serine 68 and serine 344.

The property of a protein which governs its retention in IEC is the net surface charge, which is highly pH related because of the presence of both weakly acidic and basic functional groups in proteins. The dependence of net charge of proteins on pH is a highly individual property of a protein and constitutes the basis for selectivity in IEC. At the isoelectric point, the net charge of a protein is zero and there should be no retention in IEC. However, experimental retention maps as a function of pH show that many proteins are retained on ion-exchange columns even when their net charge is zero (Figure 11), suggesting that the retention of proteins on ion-exchange stationary phases cannot be satisfactorily explained by the net charge concept alone. Deviations from this concept are mainly due to intramolecular charge asymmetry. Thus, regions of localized charges capable of interacting with oppositely charged functional groups on the surface of the stationary phase are present even at the isoelectric point.[60] In addition to the charge characteristics of the protein itself, the nature of the support surface and the displacing ion in the mobile phase are also important in determining the selectivity of an IEC separation system. The use of different displacing salts may result in retention variations of up to 100% and represents an easy and fast means of altering the selectivity of a chromatographic separation, as exemplified by the exchange of chloride by citrate as the displacing ion in the separation of soybean trypsin inhibitor and ovalbumin on a strong anion-exchange

Figure 11 Experimental retention map for ovalbumin on a strong cation-exchange (Mono S from Pharmacia) and a strong anion-exchange (Mono Q from Pharmacia) column. Ovalbumin was eluted at 1 mL min^{-1} with a gradient of 0–0.5 M sodium chloride in 20 min. (Reprinted from W. Kopaciewicz, M.A. Rounds, J. Fausnaugh, F.E. Regnier, 'Retention Model for High-performance Ion-exchange Chromatography', *J. Chromatogr.*, **266**, 3–21 (1983), Copyright 1983, with permission from Elsevier Science.)

column, which entails an increase in the separation factor from 1.50 to 2.61.[60]

6.3 Reversed-phase and Hydrophobic Interaction Chromatography

The separation of peptide mixtures, particularly from proteolytic digests, is an important part of protein characterization. Peptide mapping by HPLC is routinely performed in the study of microheterogeneity, mutational variants, and isomers present in proteins. In the RPC of peptides and proteins, acids such as trifluoroacetic acid, phosphoric acid, hydrochloric acid, formic acid, and acetic acid are frequently used as mobile phase additives for the following reasons: (1) when silica-based stationary phases are employed, protonation of residual silanol groups on the support surface at low pH diminishes unwanted ionic interactions with the basic amino acid residues; (2) small organic acids form ion pairs with these basic sites and consequently increase the hydrophobic character of a peptide or protein; and (3) acidic solvents assist in the process of unfolding and denaturing the three-dimensional structure of a polypeptide, resulting in more homogeneous species that elute as sharper and more symmetric peaks. Trifluoroacetic acid is the most commonly used acid because it is volatile (unlike phosphoric acid), it does not corrode stainless-steel parts of the HPLC apparatus (unlike hydrochloric acid), and it is UV-transparent (unlike acetic and formic acid). The chromatogram of a tryptic digest of recombinant tissue plasminogen activator, a protein of 527 amino acids, on an octadecylated silica stationary phase using trifluoroacetic acid as mobile phase additive is shown in Figure 12.

Figure 12 Reversed-phase separation of a tryptic digest of recombinant tissue plasminogen activator. Column, Nova-Pak C_{18} column from Waters, 5 µm particle size, 6 nm pore size, 150 × 3.9 mm i.d.; mobile phase, (A) 0.1% trifluoroacetic acid in water, (B) 0.08% trifluoroacetic acid in acetonitrile; linear gradient, 0–25% B in 50 min followed by 25–60% B in 35 min; flow rate, 1 mL min^{-1}; sample, tryptic map of reduced and carboxymethylated recombinant tissue plasminogen activator. (Reprinted from R.C. Chloupek, R.J. Harris, C.K. Leonhard, R.G. Keck, B.A. Keyt, M.W. Spellman, A.J.S. Jones, W.S. Hancock, 'Study of the Primary Structure of Recombinant Tissue Plasminogen Activator by Reversed-phase High-performance Liquid Chromatographic Tryptic Mapping', *J. Chromatogr.*, **463**, 375–396 (1989), Copyright 1989, with permission from Elsevier Science.)

The high selectivity and efficiency of the RPC of proteins is largely a consequence of the denaturing conditions applied (hydrophobic stationary phase, high concentration of organic solvent, low pH, elevated temperature). The potential efficiency of a 53 × 4 mm i.d. column packed with nonporous octadecylated PS/DVB is illustrated in Figure 13 by the high-resolution separation of 15 standard proteins in 13 min. The high selectivity of the separation system is reflected in the separation of the two β-lactoglobulins A and B, which differ by the substitution of only two amino acids in a total sequence of 162. β-Lactoglobulin B has a glycine at position 64 and an alanine at position 118, whereas β-lactoglobulin A contains aspartic acid and valine at the two respective positions.

The preparative purification of proteins by RPC suffers from poor recovery in terms of both total mass and biological activity. These observations are due to their strong interactions with the hydrophobic stationary phase and the strongly denaturing mobile phase conditions. HIC is an alternative chromatographic mode based on hydrophobic interactions, whereby the proteins are eluted from a weakly hydrophobic stationary phase by a decreasing salt gradient. Because the binding of the proteins to the stationary phase is weak compared with

Figure 13 High-resolution RPC of proteins. Column, octadecylated PS/DVB from Transgenomic, 2.3 µm particle size, nonporous, 53 × 4 mm i.d.; mobile phase, (A) 0.1% trifluoroacetic acid–15% acetonitrile in water, (B) 0.1% trifluoroacetic acid–60% acetonitrile in water; linear gradient, 20–85% B in 15 min; flow rate, 0.56 mL min^{-1}; temperature, 80 °C. Peak identification: RIB, ribonuclease A; INS, insulin; CYT, cytochrome *c*; LYS, lysozyme; TRY, trypsin; LALB, α-lactalbumin; STI, trypsin inhibitor; MYO, myoglobin; CON, conalbumin; HEM, hemoglobin; CHG, chymotrypsinogen A; LAC A, β-lactoglobulin A; LAC B, β-lactoglobulin B; CAT, catalase; OVA, ovalbumin. RPC, and because organic solvents are generally not used, they may be eluted without conformational changes and retain their biological activity. The main variables controlling retention in HIC are hydrophobicity of the stationary phase, stationary phase ligand density and chain length, salt identity and concentration, gradient time and flow rate, pH, and temperature.[61] Figure 14 illustrates the HIC of proteins on a hydrophilic derivatized silica stationary phase. The proteins are adsorbed at the stationary phase with 2 M ammonium sulfate and elute as the salt concentration is gradually decreased.

6.4 Metal Interaction and Affinity Chromatography

Transition metals are known to form complexes with electron-rich compounds such as the amino acids cysteine, histidine, tryptophan, lysine, and tyrosine. The different number of such amino acids and the differences in their steric accessibility in proteins can be used for their chromatographic separation. The transition metal is usually immobilized on the surface of a chromatographic support by means of a chelating functionality such as iminodiacetic acid (Figure 15a).[62] Without metal, the iminodiacetic acid bonded stationary phase is expected to function as a cation exchanger. A typical chromatogram of a protein mixture separated under ion-exchange conditions at pH 5.0 is shown in Figure 15(b). However, the retention behavior of proteins is significantly altered upon chelation of Ni(II) (Figure 15c). It can be seen that the retention of most proteins increased and the selectivity changed considerably with the immobilized metal under otherwise identical conditions. In MIC, analytes are eluted with a gradient of increasing salt concentration, where the anion can be regarded as a competitive ligand for the coordination sites of the immobilized metal. The retention of proteins in MIC depends primarily on the number of ligands at the protein surface, the type and amount of immobilized metal, the strength of the protein–metal interaction, pH, and the type and concentration of displacing ion.

AC is the chromatographic method of highest specificity for proteins.[63] The separation system is usually designed such that only one target molecule is recognized in very complex mixtures by taking advantage of highly specific biochemical interactions. Therefore, chromatographic efficiency is normally not a big issue in AC. Since

Figure 15 (a) Schematic illustration of the functional group in MIC and separation of proteins by (b) cation-exchange chromatography on iminodiacetate silica, and (c) MIC on Ni(II) iminodiacetate silica. Columns, unloaded (b) and Ni(II) loaded (c) iminodiacetate silica, 5 µm particle size, 30 nm pore size, 100 × 4.6 mm i.d.; mobile phase, (A) 25 mM phosphate, pH 5.0, (B) 0.5 M sodium chloride in (A); linear gradient, 16–100% B in 40 min; flow rate, 1 mL min^{-1}; temperature, 25 °C. Peak identification: OVA, ovalbumin; LAC A, β-lactoglobulin A; CHG, chymotrypsinogen A; CYT, cytochrome *c*; LYS, lysozyme. (Reprinted from Z. El Rassi, C. Horváth, 'Metal Chelate-interaction Chromatography of Proteins with Iminodiacetic Acid-bonded Stationary Phases on Silica Support', *J. Chromatogr.*, **359**, 241–253 (1986), Copyright 1986, with permission from Elsevier Science.)

the structure of the target molecule varies from application to application, commercially available AC media are usually preactivated supports on to which the specific ligand (antibody, receptor, antigen) is immobilized in the user's laboratory.

Figure 16(a) and (b) is a schematic illustration of the basic procedures involved in achieving a separation of proteins by AC. A sample which contains both the target molecule and impurities is loaded on the column. Adsorption of the target molecule occurs upon binding to the affinity ligand, while the impurities are washed through the column (Figure 16a). The target molecules are desorbed from the affinity stationary phase by one of the following methods (Figure 16b): (1) changing the pH, which induces the dissociation of the complex through protonation/deprotonation of basic/acidic sites involved in the biospecific interaction and/or through pH-induced conformational changes; (2) increasing the salt concentration, which weakens the electrostatic interactions between the target molecule and the affinity ligand; or (3) addition

Figure 16 Schematic illustration of AC. (a) The target molecule is adsorbed biospecifically on the column, whereas all other molecules pass the column without retention. (b) The target molecule is released from the column upon dissociation of the affinity ligand–target molecule complex.

of a competitive ligand which strongly binds either to the target molecule or the affinity ligand.

7 SEPARATION OF NUCLEIC ACIDS

Nucleic acid structures can be divided into four different types, namely single-stranded oligonucleotides (10–100 nucleotides in length), double-stranded linear DNA (10 to more than 10 000 base pairs in length), supercoiled DNA (several thousand base pairs), and single-stranded RNA. Oligonucleotides are relatively small molecules where both the hydrophilic sugar–phosphate backbone and the hydrophobic nucleobases are exposed to the solution. In double-stranded DNA, a double-helical structure secludes the hydrophobic nucleobases inside the double helix, whereas the two helical sugar–phosphate chains spiral down the outside of the double-stranded structure, presenting a polyanionic and hydrophilic surface to the solvent. Supercoiled DNA is a special form of double-stranded DNA where closed circles of double-stranded DNA are wound around each other. Most single-stranded RNAs may be considered as having a globular structure with complementary sequences forming hairpin structures.

7.1 Size-exclusion Chromatography

Although SEC generally affords longer analysis times and lower resolution of oligonucleotides and DNA fragments

than IEC, mixed-mode chromatography, or IPRPC, it offers some advantages such as simple instrumentation, isocratic elution, great freedom of buffer choice, and elution in strict order of size. Resolution of mixtures of DNA fragments is achieved by selecting a stationary phase of a suitable pore-size distribution for the discrimination of molecular masses. The linear portion of a calibration graph generated by a polymer-based stationary phase containing >100-nm pores indicates (Figure 17) that this stationary phase is suitable for separating DNA fragments ranging in size from 100 to 7000 base pairs (one base pair has a mass of approximately 660).

7.2 Anion-exchange Chromatography

To fractionate polyanions such as nucleic acids, anion-exchange chromatography is the most obvious method. The negatively charged nucleic acids interact with the positively charged functional groups of the anion-exchange stationary phase and are desorbed by a gradient of increasing salt concentration. Figure 18 shows a separation of a hydrolysate of polydeoxyadenylic acid containing oligomers from the 17-mer through approximately the 100-mer on a nonporous, polymer based anion exchanger. Baseline separation is obtained for up to about the 32-mer and peaks appear for up to the 70-mer, the whole chromatogram taking only 20 min. Although the separation of homooligomers is strictly according to chain

Figure 17 Relationship between elution volume and molecular mass in SEC of DNA fragments. Four TSKgel DNA-PW columns from TosoHaas connected in series, 10 µm particle size, >100 nm pore size, 300 × 7.8 mm i.d.; mobile phase, 0.1 M TRIS–HCl–0.3 M sodium chloride, pH 7.5; flow rate, 0.3 mL min^{-1}; sample, *Eco*RI-cleaved pBR322 DNA and *Bst*NI-cleaved pBR322 DNA. (Reprinted from Y. Kato, Y. Yamasaki, T. Hashimoto, T. Murotsu, S. Fukushige, K. Matsubara, 'Separation of Large DNA Restriction Fragments by High-performance Gel Filtration on TSKgel DNA-PW', *J. Chromatogr.*, **320**, 440–444 (1985), Copyright 1985, with permission from Elsevier Science.)

Figure 18 Anion-exchange separation of oligodeoxyadenylic acids. Two TSKgel DEAE NPR (diethylaminoethyl-derivatized hydrophilic polymer from TosoHaas) columns connected in series, 2.5 µm particle size, nonporous, 35 × 4.6 mm i.d.; mobile phase, (A) 20 mM TRIS–HCl, pH 9.0, (B) 1 M sodium chloride in (A); linear gradient, 25–100% B in 60 min; flow rate, 1 mL min^{-1}; temperature, 25 °C. Peaks are identified by the number of adenosine units in the oligomer. (Reprinted from Y. Kato, T. Kitamura, A. Mitsui, Y. Yamasaki, T. Hashimoto, T. Murotsu, S. Fukushige, K. Masubara, 'Separation of Oligonucleotides by High-performance Ion-exchange Chromatography on a Nonporous Ion Exchanger', *J. Chromatogr.*, **447**, 212–220 (1988), Copyright 1988, with permission from Elsevier Science.)

length, the base sequence of heterooligonucleotides has a significant impact in retention, most probably due to secondary interactions with the stationary phase and conformational influences. On a TSKgel DEAE NPR stationary phase, the retention of 12–18-mer oligonucleotides containing different bases increased in the order adenosine < thymidine < cytidine, whereas on a nonporous, quaternized PS/DVB anion exchanger the elution order was cytidine < adenosine < thymidine.[64]

The same stationary phase as used for the high-resolution separation of oligonucleotides can also be applied to the separation of double-stranded DNA fragments, as illustrated in Figure 19 by the fast separation of 22 DNA fragments of a 1-kilobase-pair ladder with fragments ranging in size from 75 to 12 216 base pairs. This separation demonstrates that IEC can separate DNA fragments with high resolution over an extremely broad size range in a fraction of the time that is needed for a size-exclusion separation (10 versus 130 min, compare Figure 17). The separation principle of anion-exchange chromatography implies that elution order is determined only by size because with double-stranded DNA, the hydrophobicity of the nucleobases is expected to have a minor influence on retention because they are secluded inside the double

Figure 19 Anion-exchange separation of DNA fragments. Column, TSKgel DEAE NPR (diethylaminoethyl-derivatized hydrophilic polymer from TosoHaas), 2.5 μm particle size, nonporous, 75 × 4.6 mm i.d.; mobile phase, (A) 20 mM TRIS–HCl, pH 9.0, (B) 1 M sodium chloride in (A); linear gradient, 50–75% B in 15 min; flow rate, 1 mL min^{-1}; temperature, 25 °C. Peaks are identified by the number of base pairs in the DNA fragment. (Reprinted from C.G. Huber, 'Micropellicular Stationary Phases for High-performance Liquid Chromatography of DsDNA', *J. Chromatogr. A*, **806**, 3–30 (1998), Copyright 1998, with permission from Elsevier Science.)

Figure 20 IPRPC separation of oligodeoxyadenylic acids. Column, octadecylated PS/DVB from Transgenomic, 2.3 μm particle size, nonporous, 50 × 4.6 mm i.d.; mobile phase, (A) 0.1 M triethylammonium acetate, pH 7.0, (B) 25% acetonitrile in (A); linear gradient, 22–33% B in 10 min, 33–36% B in 6 min, 36–45% B in 9 min; flow rate, 1 mL min^{-1}; temperature, 50 °C. Peaks are identified by the number of adenosine nucleotides in the oligomer. (Reproduced from C.G. Huber, E. Stimpfl, P.J. Oefner, G.K. Bonn, 'A Comparison of Micropellicular Ion-exchange and Reversed-phase Stationary Phases for HPLC of Oligonucleotides', *LC-GC*, **14**, 114–127 (1996), by permission of Advanstar Communications.)

helix. However, anion-exchange separation of double-stranded DNA fragments on a variety of different stationary phases has suffered from inversions in retention time as a function of chain length, preventing its use for size-accurate fragment identification (compare, e.g. the elution order of the 220 and 201 base-pair fragments or the 1636 and 1018 base-pair fragments in Figure 19). A more length-relevant separation of DNA fragments at the cost of lower resolution is feasible when a gradient of tetraethylammonium chloride is applied instead of sodium chloride.[65]

7.3 Ion-pair Reversed-phase Chromatography

Retention of nucleic acids is effected predominantly by electrostatic interactions both in anion-exchange chromatography and in IPRPC. However, the two chromatographic modes differ in the way in which the surface potential is generated at the stationary phase. Whereas anion exchangers have the charged functional groups covalently bound to the surface, the amphiphilic ions generating the surface potential in IPRPC are adsorbed through hydrophobic interactions on the surface of a reversed-phase stationary phase. The surface concentration of the amphiphile strongly depends on the concentration of organic modifier in the eluent, which offers a simple means of controlling the retention of the analytes in IPRPC. The most popular amphiphiles for the IPRPC of nucleic acids are trialkylammonium and tetraalkylammonium ions, where the alkyl chains vary from methyl to butyl. Common gradient formers are acetonitrile, methanol, and 2-propanol.

Figure 20 depicts the separation of a homologous series of oligodeoxyadenylic acids by IPRPC on a nonporous, octadecylated PS/DVB stationary phase. With a total separation time of 28 min, baseline separation is obtained up to about the 50-mer and peaks appear up to the 90-mer. Compared with anion-exchange chromatography, the influence of base composition on the retention behavior of oligonucleotides is more pronounced in IPRPC owing to additional hydrophobic interactions of the nucleobases with the hydrophobic stationary phase, the elution order of 4-mer homooligonucleotides being tetradeoxyguanosine < tetradeoxycytidine < tetradeoxyadenosine < tetradeoxythymidine.[64]

IPRPC is also suitable for the separation of double-stranded DNA fragments. Figure 21 shows the chromatogram of a mixture of four different restriction digests of the plasmids pBR322 and pBR328 containing 45 DNA fragments. Of these, 39 fragments are of different size and are separated into 33 at least partially resolved peaks. Compared with anion-exchange chromatography, IPRPC can separate DNA fragments up to a chain length of 2000

Figure 21 High-resolution IPRPC separation of DNA fragments. Column, octadecylated PS/DVB from Transgenomic, 2.3 µm particle size, nonporous, 50 × 4.6 mm i.d.; mobile phase, (A) 0.1 M triethylammonium acetate, pH 7.0, (B) 25% acetonitrile in (A); linear gradient, 38–54% B in 10 min, 33–36% B in 7 min, 54–62% B in 8 min, 62–71% B in 15 min; flow rate, 0.75 mL min^{-1}; temperature, 50 °C; sample, *Hae*III-cleaved pBR322 DNA, *Alu*I-cleaved pBR322 DNA, *Bgl*I-cleaved pBR328 DNA, and *Hinf*I-cleaved pBR328 DNA. Peaks are identified by the number of base pairs in the DNA fragment.

base pairs with higher resolution, whereas the former can better separate long DNA fragments (>2000 base pairs). In IPRPC, the retention of double-stranded nucleic acids is size dependent to a very high degree, which allows the calculation of fragment size from retention data with an accuracy of better than 3.2%.[66] Moreover, the correlation between size and retention time is almost linear up to 500 base pairs and then slowly levels off up to 2000 base pairs.

One important additional feature of IPRPC is the sequence-dependent retention of double-stranded DNA fragments at temperatures higher than 55 °C due to partial denaturation.[67] The temperature at which the separation of the two DNA strands begins is determined by the total number and extent of repetitive AT tracts in a DNA fragment and thus depends on the DNA sequence. The perturbation of the helical structure in partially denatured DNA fragments as a consequence of opening of the double strand results in decreased retention compared with completely double helical fragments of the same length because of a smaller contact area with the stationary phase.

7.4 Mixed-mode Chromatography

With mixed-mode chromatography, the separation of the analytes relies upon at least two different modes of interaction between the solute and the stationary phase. Although with many types of stationary phases the separation can be regarded as the result of mixed-mode processes, generally the additional modes of interaction are a minor effect and can be minimized through the appropriate choice of mobile phase parameters. In order to provide solute retention by mixed interactions, it is necessary that the stationary phase be multifunctional in character. In the case of nucleic acids, mixed electrostatic and hydrophobic interaction are most successfully employed. The two methods for the preparation of mixed-mode stationary phases for electrostatic and hydrophobic interaction are the introduction of hydrophobic moieties on to an ion-exchange packing (e.g. through alkylation of the amino groups of aminopropylsilica) or the introduction of sites for electrostatic interaction into a reversed-phase stationary phase (e.g. through adsorption of methyltrioctylammonium chloride on octadecyl silica).[68] Mixed-mode supports have proven to be very valuable for separating tRNAs by mixed-mode chromatography. Elution of tRNAs is performed with a combined gradient of increasing ammonium acetate concentration and increasing pH.

Figure 22 AC of polyadenosine mRNA from *Saccharomyces*. Column, silica gel, derivatized with $(dT)_{18}$, 7 µm particle size, 30 nm pore size, 30 × 4.6 mm i.d.; mobile phase, (A) 10 mM phosphate, pH 7.0–1 M sodium chloride, (B) 5 mM phosphate, pH 7.0; temperature and salt gradient as indicated; flow rate, 1 mL min^{-1}. Peak identification: see text. (Reprinted from T.A. Goss, M. Bard, H.W. Jarrett, 'High-performance Affinity Chromatography of Messenger RNA', *J. Chromatogr.*, **588**, 157–164 (1991), Copyright 1991, with permission from Elsevier Science.)

7.5 Affinity Chromatography

The AC of nucleic acids involves the highly selective base pairing of two complementary polynucleotide strands. By attaching single-stranded oligonucleotides to a chromatographic support, nucleic acids containing a sequence complementary to the immobilized sequence are retained by the column.[69] Figure 22 shows as an example the selective isolation of mRNA from *Saccharomyces* containing polyadenosine tracts at their 3′-ends. Using a silica stationary phase with an immobilized oligodeoxythymidine 18-mer [$(dT)_{18}$] and a combination of salt and temperature gradients, mRNA can be purified in as little as 8 min. The first, unretained peak contains rRNA and nonpolyadenylated mRNA and the second peak contains mRNA with short stretches of polyadenosine with less than 15 adenosine units. The third peak represents the bulk of the polyadenosine mRNA with tail lengths of 15–80 units. The fourth peak contains mRNA with long polyadenosine tails of about 80 units.

8 SEPARATION OF OLIGO- AND POLYSACCHARIDES

Oligo- and polysaccharides can have an enormous number of possible structures because of the various configurations possible for monosaccharides, their variable linkage forms, the possibility of α- and β- anomers at the glycoside linkage, and their different branching patterns. While the linkage of three different amino acids can result in only six different tripeptides, three different carbohydrates can theoretically form more than 700 trisaccharides. Furthermore, saccharides are diversified by the presence of nonglycosyl substituents. Oligosaccharides have covalent structures of 2–25 usually different monosaccharide residues joined by glycosidic linkages, resulting in linear, branched, or cyclic chains. Polysaccharides are polymeric forms of repeating mono-, di-, or tetrasaccharides. Naturally occurring polysaccharides may range in molecular mass from a few thousand to several million.

8.1 Size-exclusion Chromatography

SEC is the method of choice for the separation of high molecular mass polysaccharides.[32] With appropriate stationary phases of smaller pore size, it is also applicable to the separation of oligosaccharides, although possibly with lower resolution than that offered by IEC. With saccharides, having a high portion of hydroxyl and other polar groups, interaction with a polar stationary phase is likely to induce unwanted adsorption unless the ionic strength of the mobile phase is high enough (0.1–1 M) to exclude such interaction. SEC has found application in the carbohydrate field mainly as a means of fractionation and molecular mass distribution analysis of polysaccharides. Calibration is a general problem in SEC of polysaccharides because standard substances of known molecular mass are not readily available for all structural types of polysaccharides. However, advances in detection methods such as LALLS detection largely overcome this drawback and, furthermore, enable the extraction of information on polymer branching and conformation from size-exclusion data.

8.2 Normal- and Reversed-phase Chromatography

By virtue of their two different retention mechanisms, NPC and RPC are complementary separation techniques and should be used in conjunction for the isolation and analysis of oligosaccharides. A normal-phase separation of maltooligosaccharides is depicted in Figure 23. The substances are eluted in the order of their increasing molecular mass. Baseline separation up to the 17-mer is obtained on an aminopropylsilica stationary phase with a gradient of 25–75% water in acetonitrile.[70] The oligosaccharides are in the form of their 4-nitrophenylglycosides which are detected by their absorbance at 300 nm. Alternatively, the same sample can be separated by RPC on an octadecylsilica stationary phase (ODS-Hypersil from Shandon) with a gradient

Figure 23 Separation of 4-nitrophenyl-derivatized α-D-maltooligomers by NPC. Column, Hypersil APS-2 (aminopropyl-modified silica gel) from Shandon, 5 μm particle size, 12 nm pore size, 250 × 4 mm; i.d. mobile phase, (A) acetonitrile, (B) water; linear gradient, 25–75% B in 60 min; flow rate, 1.5 mL min^{-1}. Numbers on peaks indicate number of glucose units. (Reprinted from C. Niemann, W. Saenger, R. Nuck, B. Pfannemüller, 'HPLC of 4-Nitrophenyl-α-D-malto-oligosaccharides', *Carbohydr. Res.*, **215**, 15–23 (1991), Copyright 1991, with permission from Elsevier Science.)

Figure 24 Separation of linear maltooligosaccharide oligomers of up to 21 glucose residues by anion-exchange chromatography with pulsed ELCD. Column, PS/DVB with trimethylammonium groups, 2.1 µm particle size, nonporous; mobile phase, (A) 50 mM sodium hydroxide, (B) 50 mM sodium hydroxide–1 M sodium acetate; linear gradient, 0–20% B in 20 min; flow rate, 0.5 mL min^{-1}; detection, PAD, $E_1 = 100$ mV ($t_1 = 300$ ms), $E_2 = 600$ mV ($t_2 = 120$ ms), $E_3 = -6$ mV ($t_3 = 300$ ms). Numbers on peaks indicate number of glucose units. (Reprinted from C. Corradini, D. Corradini, C.G. Huber, G.K. Bonn, 'Synthesis of a Polymeric-based Stationary Phase for Carbohydrate Separation by High-pH Anion-exchange Chromatography with Pulsed Amperometric Detection', *J. Chromatogr. A*, **685**, 213–220 (1994), Copyright 1994, with permission from Elsevier Science.)

from 4 to 90% acetonitrile in water with similar, but slightly lower, resolution.[70]

8.3 Ion-exchange Chromatography

Since carbohydrates are weak acids with pK_a values ranging from 12 to 14 they dissociate under highly alkaline conditions and can be separated directly at high pH by anion-exchange chromatography. Elution at high pH allows the separation of saccharides as their oxoanions. This approach cannot be used with silica-based stationary phases owing to their poor stability at high pH. Therefore, a range of polymeric, nonporous ion exchangers has been developed by Dionex. These stationary phases consist of 5–10-µm nonporous core particles on to which a layer of quaternary ammonium anion-exchange microbeads (<0.1 µm) is attached by electrostatic interactions, providing rapid mass transport, high ion-exchange capacity, and high chemical and mechanical stability. High-pH anion-exchange chromatography is uniquely able to resolve structural isomers of oligosaccharides derived from glycoproteins or complex biological samples. Detection of carbohydrates at high pH conditions poses a problem. Pre- and postcolumn derivatization methods have been largely replaced by PAD at gold electrodes, which works well under alkaline conditions. Moreover, PAD is characterized by low detection limits and relatively high specificity for compounds with hydroxyl groups. The high-pH anion-exchange separation of maltooligosaccharides on a nonporous PS/DVB stationary phase with covalently bound trimethylammonium groups is shown in Figure 24. The oligomers are eluted with a gradient of 0–0.2 M sodium acetate in 50 mM sodium hydroxide and baseline resolution of the oligomers is feasible at least up to the 20-mer.

8.4 Metal Interaction Chromatography

Separations of mono- and oligosaccharides on 5–10% cross-linked PS/DVB sulfonic acid cation exchangers in the hydrogen form are mainly due to the size-exclusion effect in the swollen polymer gels.[32] The degree of cross-linking of a resin is important because separation can only take place when the sample molecules penetrate at least partially into the matrix. For this reason, cation-exchange resins for the analysis of oligosaccharides usually have

Figure 25 Separation of acid-hydrolyzed corn syrup on a silver-loaded cation-exchange resin. Column, Hamilton HC-50 5% cross-linked PS/DVB resin, 10–15 µm particle size, 71% silver form; mobile phase, water; flow rate, 0.55 mL min^{-1}; temperature, 85 °C. Numbers on peaks indicate number of glucose units. (Reprinted from H.D. Scobell, K.M. Brobst, 'Rapid High-resolution Separation of Oligosaccharides on Silver Form Cation-exchange Resins', *J. Chromatogr.*, **212**, 51–64 (1981), Copyright 1981, with permission from Elsevier Science.)

a lower degree of cross-linking than those optimized for the separation of monomers. Silver ions are known to form fairly stable monodentate complexes with most monosaccharides.[32] This complex formation also brings about greater retention of oligosaccharides on silver-loaded cation-exchange resins and allows more species to be resolved from the excluded high molecular mass polysaccharides. In the complex formation of saccharides with metal ions, the hydroxyl groups are thought to form coordinate bonds with the metal ion. The stability of the complexes depends both on the type of metal ion and on the configuration of the hydroxyl groups in the saccharides. The separation of oligosaccharides obtained by the hydrolysis of corn syrup is illustrated in Figure 25. Oligomers up to the 10-mer are separated on a 5% cross-linked cation exchanger that is loaded with 71% silver ions.

9 MODERN TRENDS AND FUTURE DEVELOPMENTS

9.1 Miniaturization of Separation Systems

One of the clear trends in science and technology is miniaturization, which is also a permanent goal in analytical chemistry, where the growing interest in analyzing minute samples of high complexity is the driving force for the rapid development of miniaturized techniques.[71] One of the most important innovations in the field of miniaturized separation has been the introduction of fused-silica capillaries, which gave birth to several miniaturized separation techniques including capillary gas chromatography (GC), capillary LC, capillary electrophoresis (CE), and capillary electrochromatography (CEC) (see **Microscale High-performance Liquid Chromatography and the Evolution of Capillary Electrochromatography**). Basically, four major advantages connected with the use of smaller dimensions in LC separation techniques can be specified: (1) better resolving power can be accomplished in a shorter time; (2) smaller samples can be analyzed; (3) on-line conjugation to MS is feasible; and (4) expenses connected with consumption and disposal of materials are decreased.

Miniaturization of column technology is usually the first step in the development of a miniaturized LC separation system. Today, four major types of microcolumns can be distinguished:[72] (1) open-tubular microcolumns; (2) partially packed capillary columns; (3) tightly packed capillary columns; and (4) continuous-bed capillary columns. Column inner diameters down to 5–20 μm have been realized with these types of capillary columns. The downscaling factor, which corresponds to the square of the ratio of the column diameters, for the reduction of the column inner diameter, e.g. from the traditional 4.6 mm to 25 μm, is 33 856, which means that all parameters related to the volume, including volumetric flow rate, injection volume, and detection volume, have to be divided by the downscaling factor. Thus, a capillary column of 25 μm i.d. is operated at a flow rate of around 30 nL min^{-1} and a few tenths of a nanoliter are injected, allowing the chromatographic analysis of attomole to zeptomole amounts of biopolymers.

However, the low flow rates and detection volumes represent considerable challenges to reliable instrumentation for miniaturized LC, and miniaturized versions of conventional instruments frequently fail to provide the required performance. Therefore, alternative principles for pumping and detecting devices, such as pumps based on thermal expansion[73] or electroosmosis,[74] and detection devices based on microelectrodes, laser light,[75] or MS[74] have been developed. One of the strongest supports in microtechnology is provided by microelectronics. Advances in manufacturing processes, namely silicon micromachining techniques, are the basis for miniaturization of liquid-phase separation techniques down to the submicrometer level. Figure 26 shows an electron micrograph of the inlet and part of the chromatographic bed of a microfabricated column which was machined by lithography on a silicon wafer. Hundreds of such column structures on a single wafer are possible based on the ease with which millions of submicrometer-sized structural features are micromachined into silicon wafers. This represents a great potential for multiplexing of miniaturized liquid-phase separation technology.

Tait, F.E. Regnier, 'Fabrication of Nanocolumns for Liquid Chromatography', *Anal. Chem.*, **70**, 3790–3797 (1998), Copyright 1998 American Chemical Society.)

9.2 Multidimensional Separation of Biopolymers and Coupling to Mass Spectrometry

Although single-stage chromatographic separation systems offer high selectivity and resolving power for biopolymers, the total peak capacity may not suffice to separate all the components of interest contained in complex mixtures of biological origin. A practical means of increasing the selectivity of a separation system is the use of two or more separation stages, resulting in the multidimensional separation of a biopolymer mixture.[76] The two criteria for multidimensional separation are that the sample components are displaced by two or more separation techniques based on different separation mechanisms and that the components separated by any single separation dimension must not be recombined in any further separation dimension. The two separation dimensions should ideally be orthogonal, i.e. separate the analyte according to different molecular properties. The key feature of a multidimensional system is that all analytes composing the initially injected sample are eventually transferred to all further separation stages.

In column LC, utilization of the total available separation selectivity would require a large number of secondary columns, so that all the sample cuts taken while eluting from the first dimension could be transferred to the second dimension. In practice, however, definite fractions of the separations taken in the first dimension are studied in the second dimension, a technique that is conventionally termed coupled-column LC. If the timescale for the first dimension is of the order of a few minutes for one eluting peak, whereas that for the second dimension is of the order of a few seconds per peak, analytes eluting from the first stage of separation can be sampled and analyzed in real time in the second stage without loss of the separation in the first dimension. The requirement for such a fast separation in the second dimension is ideally met by RPC. Therefore, the most frequently used combinations of separation dimensions for the multidimensional LC separation of protein mixtures are SEC/RPC and IEC/RPC.

MS is generally viewed as a spectroscopic technique yielding both the molecular mass and structural information from fragmentation and is used as a powerful detection method for the analytes separated by LC (see **Liquid Chromatography/Mass Spectrometry**). However, it can also be viewed as a separation technique distinguishing between different mass-to-charge ratios. Therefore, according to the definition given above, conjugation of LC and MS represents a multidimensional separation system. Two MS ionization techniques for biopolymers are considered to be most compatible with the flow rates identified with microscale liquid-phase separations: CFFAB and ESI. It is more difficult to couple MALDI directly to liquid-phase separations, because samples have to be mixed with a matrix and dried on a solid surface before insertion into the mass spectrometer. Therefore, MALDI MS is mainly used as off-line detection of fractions collected from LC.

Coupled reversed-phase HPLC with ESIMS has emerged as a very powerful tool for the identification of known protein sequences and also for the de novo sequencing of proteins. The most effective method is the combination of chemical or proteolytic digestion of a protein followed by reversed-phase separation and identification of the resulting peptide sequences by tandem MS. In tandem MS, ions of a single mass-to-charge ratio are selected for transmission through the first mass analyzer and into a cell for collision-induced dissociation, where the peptides fragment to create patterns characteristic of a specific amino acid sequence. These are subsequently detected by means of a second mass analyzer. With the help of a computer algorithm, the experimental patterns can be compared and matched with calculated patterns obtained from databases containing the sequences of all known proteins. This method allows the rapid and fully automated identification of the proteins in whole cell lysates from uninterpreted tandem mass spectra of tryptic peptides by comparison with sequences in a protein database.[77] Unknown protein sequences can be deduced from the sequence-specific pattern in the mass spectrum of the fragmented peptide.

A schematic diagram of an on-line multidimensional separation system for proteins is illustrated in Figure 27.

Figure 27 Schematic diagram of an on-line multidimensional separation system for proteins. (Reprinted with permission from G.J. Opiteck, K.C. Lewis, J.W. Jorgenson, R.J. Anderegg, 'Comprehensive On-line LC/LC/MS of Proteins', *Anal. Chem.*, **69**, 1518–1524 (1997), Copyright 1997 American Chemical Society.)

The three applied separation dimensions involve cation-exchange chromatography, RPC, and MS. Sample components eluting from the cation-exchange column are sampled by an eight-port valve and subsequently injected on to a reversed-phase column. The eluate from RPC is split into a UV detector and an ESI mass spectrometer. One 120-min cation-exchange run is sampled by 48 individual 150-s duration reversed-phase runs and mass spectra from m/z 1000 to 2000 are recorded every 2 s. The peaks eluting from the cation-exchange column are approximately 6 min wide. With a time between the injection peak and the last-eluting peak of 100 min, a maximum peak capacity of 16 in the first dimension can be achieved. A peak width of about 5 s and an available elution time of 60 s give a peak capacity of 32 in the second dimension. Taking the inherent peak capacity of MS as 5, because it can identify at least this number of components in the m/z 1000–2000 mass range, the peak capacity of the entire three-dimensional system amounts to >2500, which is sufficient even for complicated biological mixtures.

9.3 Capillary Electrochromatography

CEC is an electrokinetic separation technique that is expected to combine the versatility offered by HPLC with the high plate efficiency of CE (see **Microscale High-performance Liquid Chromatography and the Evolution of Capillary Electrochromatography**).[78] The technique employs fused-silica capillaries packed with a stationary phase that has fixed charges at the surface. Thus, upon application of a high electric field, flow of eluent across the column is generated and maintained by electro-osmotic means. The diffuse part of the electrical double layer, which exists at all interfaces between a solid and an electrolyte solution, responds to the driving force of the electric field generating the flat flow profile characteristic for electroosmotically driven flow.

CEC promises much higher plate efficiencies than microcolumn HPLC with packed capillary columns. Furthermore, CEC offers a higher sample loading capacity and a wider range of selectivity than CE. The unique electro-osmotic flow field allows the use of long capillary columns packed with small particles, resulting in significant gains in peak capacity. CEC is applicable to the analysis of neutral and charged compounds. The sample components are separated on the basis of differences in their chromatographic partitioning between the mobile and the stationary phase and, if charged, also differences in their electrophoretic mobilities. The potential of CEC for the analysis of biopolymers lies in increased peak capacity owing to higher selectivity because of the two different separation mechanisms involved (chromatography and electrophoresis) and higher efficiency because of the flat electro-osmotic flow profile. Figure 28 shows the separation of standard proteins by gradient reversed-phase CEC in a monolithic capillary column.

Figure 28 Reversed-phase gradient electrochromatographic separation of proteins on a continuous-bed stationary phase. Column, fused-silica tube filled with a porous methacrylamide–stearyl methacrylate–dimethyldiallylammonium chloride monolithic polymer, 80 × 0.05 mm i.d.; mobile phase, (A) 5 mM phosphate pH 2.0–5% acetonitrile, (B) 5 mM phosphate pH 2.0–80% acetonitrile; linear gradient, 0–100% B in 25 min; applied voltage, 5.5 kV. Peak identification: RIB, ribonuclease A; CYT, cytochrome *c*; LYS, lysozyme; CHG, chymotrypsinogen A. (Reprinted with permission from C. Ericson, S. Hjerten, 'Reversed-phase Electrochromatography of Proteins on Modified Continuous Beds Using Normal-flow and Counterflow Gradients. Theoretical and Practical Considerations', *Anal. Chem.*, **71**, 1621–1627 (1999), Copyright 1999 American Chemical Society.)

ABBREVIATIONS AND ACRONYMS

AC	Affinity Chromatography
CE	Capillary Electrophoresis
CEC	Capillary Electrochromatography
CFFAB	Continuous-flow Fast Atom Bombardment
CI	Chemical Ionization
EI	Electron Ionization
ELCD	Electrochemical Detection
ESI	Electrospray Ionization
ESIMS	Electrospray Ionization Mass Spectrometry
FAB	Fast Atom Bombardment
FL	Fluorescence
GC	Gas Chromatography
HIC	Hydrophobic Interaction Chromatography

HPLC	High-performance Liquid Chromatography
IEC	Ion-exchange Chromatography
IPRPC	Ion-pair Reversed-phase Chromatography
LALLS	Low-angle Laser Light Scattering
LC	Liquid Chromatography
MALDI	Matrix-assisted Laser Desorption/ Ionization
MIC	Metal Interaction Chromatography
MS	Mass Spectrometry
NPC	Normal-phase Chromatography
PAD	Pulsed Amperometric Detection
PEEK	Poly(ether ether ketone)
PS/DVB	Poly(styrene/divinylbenzene)
PTFE	Poly(tetrafluoroethylene)
RA	Radioactivity
RPC	Reversed-phase Chromatography
SEC	Size-exclusion Chromatography
TRIS	Tris(hydroxymethyl)aminomethane
UV	Ultraviolet
UV/VIS	Ultraviolet/Visible
VIS	Visible

Over the past two decades, capillary electrophoresis (CE) has emerged as a family of powerful and versatile separation techniques. The electrically driven flow profiles generated in CE provide, routinely, separation efficiencies of 10^5 theoretical plates. Although theory predicts that the achievable separation efficiencies will be greatest for macromolecules with small diffusion coefficients, CE has also been successful in the analysis of small molecules, such as inorganic ions. Strategies to increase separation efficiencies on-line have involved sample stacking and isotachophoretic techniques. The former promotes higher separation efficiencies based on differences in conductivity between the background electrolyte (BGE) and the sample buffer; the latter utilizes a discontinuous buffer system to create discrete solute zones. The instrumentation employed in CE is simple in design and is compatible with a variety of detection modes, including ultraviolet/visible (UV/VIS) absorbance, fluorescence, electrochemistry, mass spectrometry (MS), and chemiluminescence (CL). CE methodologies can be miniaturized on to a silicon wafer and integrated with sample preparation and chemical reactions. In addition to free-solution capillary electrophoresis (FSCE) utilizing a BGE and potentially a variety of BGE additives, several alternative separation modes have been developed and implemented. These include micellar electrokinetic chromatography (MEKC), capillary isoelectric focusing (cIEF), size-sieving capillary electrophoresis (SSCE), and capillary electrochromatography (CEC). Some of these separation modes have been adapted from the slab gel electrophoresis (SGE) format, or are reminiscent of separation mechanisms in liquid chromatography (LC). Currently, one of the greatest challenges in CE involves the maintenance of the capillary surface to provide reproducible electro-osmotic flow (EOF) and significantly reduce capillary wall interactions. According to the mode of separation employed and the characteristics of the solutes to be analyzed, both covalent and noncovalent (dynamic) capillary wall modifications have been demonstrated.

1 HISTORICAL BACKGROUND

Fundamental developments in the understanding of electrolysis, the electrical double layer, displacement electrophoresis, moving boundary electrophoresis, and other phenomena over the course of a 200-year period led to the emergence of CE as a family of powerful separation techniques. In 1967, Hjerten was the first to report free solution electrophoresis, conducted in 3-mm inner diameter (ID) capillary tubes.[1] The full advantages of this technique could not be realized until methods to introduce smaller quantities into the capillary tubes were developed to avoid sample overloading. In addition, the use of narrower bore capillary tubing (25–100 μm ID), with greater heat dissipation, would allow the use of higher field strengths (up to 900 V cm^{-1}) for faster and more efficient separations. In 1981, these advantages were realized by Jorgenson and Lukacs in what is considered the first report of modern FSCE or capillary zone electrophoresis (CZE).[2] Since then, other landmark developments have been made including the development of MEKC,[3] the development of

Encyclopedia of Analytical Chemistry

microchip CE,[4] and the development of CEC.[5] We are now closing in on the second decade of modern CE separations, performed in narrow-bore fused-silica tubing. Currently, CE pervades many areas of analysis encompassing organic, inorganic, environmental, pharmaceutical, and biotechnological applications. Initially it was predicted that CE would replace modern LC in terms of solving difficult separation problems. However CE, being fundamentally different in its principle of separation, appears to complement separations performed using LC. Currently, commercial CE equipment is in its third generation, utilizing microtiter plates for high sample throughput and appropriate interfaces for MS detection.

2 PRINCIPLES OF CAPILLARY ELECTROPHORESIS

2.1 Theory

The electrophoretic mobility, μ_{ep}, of an ionic species migrating through a medium in an electrical field is directly proportional to electrical forces and inversely proportional to frictional forces acting on the ion (Equation 1):

$$\mu_{ep} \propto \frac{\text{electrical force } (F_e)}{\text{frictional force } (F_f)} \tag{1}$$

In an electrical field, ions are accelerated by the electrical force F_e, which is a function of field strength, E, and charge of the ion, q (Equation 2):

$$F_e = qE \tag{2}$$

The opposing frictional force acting on a spherical species is defined by Equation (3):

$$F_f = -6\pi\eta r v \tag{3}$$

where η is the viscosity of the electrophoretic medium, r is the radius of the solvated species, and v is its velocity. The ionic species reaches a steady state when electrical forces are balanced with frictional forces. Hence, equating Equations (2) and (3), electrophoretic mobility can be defined according to Equation (4):

$$\mu_{ep} = \frac{q}{6\pi\eta r} \tag{4}$$

Electrophoretic mobility is also the proportionality constant between the electrophoretic velocity and the applied field strength, E (Equation 5):

$$v_{ep} = \mu_{ep} E = \mu_{ep} \frac{V}{L_t} \tag{5}$$

where V is the applied voltage and L_t is the total capillary length. The apparent mobility, μ_{app}, of a species is the vector sum of its electrophoretic mobility, μ_{ep}, and the electro-osmotic mobility, μ_{eof}, due to the presence of EOF inside the capillary (Equation 6):

$$\mu_{app} = \mu_{ep} + \mu_{eof} \tag{6}$$

EOF refers to the migration of fluids along the length of the capillary. In a buffer-filled, fused-silica capillary, an electrical double layer is established at the interface of the electrolyte solution and the fused-silica capillary surface (Figure 1). The weakly acidic silanol groups at the capillary surface exist in either the protonated or the deprotonated form according to the following chemical equilibrium (Equation 7):

$$SiOH_{(s)} \rightleftharpoons SiO_{(s)}^{-} + H_{(aq)}^{+} \tag{7}$$

At buffer pH values greater than approximately 2, the capillary wall is negatively charged. Cations surrounded by their waters of hydration are strongly attracted to and partially neutralize the negatively charged silanol sites, forming the compact layer. A diffuse layer, consisting of

Figure 1 Electrical double layer at the capillary wall and creation of EOF (N = neutral solute). (Reproduced by permission of Academic Press, Inc., from A. Weston, P.R. Brown, 'Capillary Electrophoresis', *HPLC and CE: Principles and Practice*, Academic Press, San Diego, Chapter 4, 138, 1997.)

hydrated cations, anions, and neutral species, is formed adjacent to the compact layer, neutralizing the remaining negative charge. Under the influence of a longitudinally applied electrical field, the diffuse layer and the bulk solution migrate toward the negatively charged cathode, generating EOF. The zeta potential, ζ, is the potential formed across the two layers of cations at the capillary wall and is defined according to Equation (8):

$$\zeta = \frac{4\pi\delta e}{\varepsilon} \tag{8}$$

The zeta potential is a function of the thickness of the double layer, δ, the charge per unit of surface area, e, and the dielectric constant of the electrophoretic medium, ε. The thickness of the double layer is a function of buffer composition and is independent of the applied potential. The EOF velocity of a buffer system is given by Equation (9):

$$v_{\text{eof}} = \left(\frac{\varepsilon\zeta}{\eta} \quad E \right. \tag{9}$$

demonstrating that the magnitude of EOF may be modified by altering characteristics of the BGE, such as its pH, ionic strength, and viscosity. Note that EOF velocity is independent of the capillary dimensions.

Cations will migrate toward the negatively charged electrode (the cathode); anions will migrate toward the positively charged electrode (the anode) unless EOF is sufficient in magnitude to reverse the direction of their migration. Neutral species demonstrate no inherent electrophoretic mobility and hence migrate at the EOF velocity. Therefore, EOF can be determined for a particular system by introducing a neutral solute and observing its migration time, t, as given in Equation (10):

$$t = \frac{L_t L_{\text{d}}}{\mu_{\text{app}} V} \tag{10}$$

where L_t is the total capillary length, L_{d} is the effective capillary length from the injection end of the capillary to the detector, μ_{app} is the apparent mobility, and V is the applied voltage. EOF may be effectively eliminated by covalently or dynamically coating the capillary surface, and in that event $\mu_{\text{app}} = \mu_{\text{ep}}$.

2.2 Separation Parameters and Peak Shape

At the point of injection, a sample zone will be infinitesimally narrow. As migration through the capillary proceeds, a concentration gradient will be encountered as a function of time, t, and the distance migrated from the initial point, x, to generate a peak Gaussian in shape that can be described by Equation (11):[6]

$$C_{x,t} = \frac{k}{2(D\pi t)^{0.5}} \exp -\frac{(x - v_{\text{ep}}t)^2}{4Dt} \tag{11}$$

where $C_{x,t}$ is the solute concentration, k is a constant, D is the diffusion coefficient of the solute, and v_{ep} is the electrophoretic velocity of the solute. Integration of Equation (11) yields a mathematical expression that describes the resulting concentration–distance profile. The electrophoretic peak width is influenced directly by the shape of the solute profile within the capillary. Peak width is often measured as variance, σ, which is the standard deviation for a Gaussian distribution. Variance is related to the diffusion coefficient of the analyte, D, and the time, t, that the solute is allowed to diffuse from an infinitesimally narrow zone (Equation 12):

$$\sigma^2 = 2Dt \tag{12}$$

Combining Equations (10) and (12) yields a description of peak variance in relation to the apparent electrophoretic mobility of the solute (Equation 13):

$$\sigma^2 = \frac{2DL_{\text{d}}}{\mu_{\text{app}} E} \tag{13}$$

The theoretical plate height, H, is the proportionality constant between the variance of an electrophoretic peak and the distance that the corresponding solute zone has traveled through a capillary (Equation 14):

$$H = \frac{2Dt}{L_{\text{d}}} = \frac{2DL_t}{\mu_{\text{app}} V} \tag{14}$$

The concept of theoretical plate height was developed originally to describe separation efficiency in chromatographic techniques. Later, this concept was adapted by Giddings to electrophoretic techniques.[7] The van Deemter equation (Equation 15) summarizes the dependence of plate height on on-column band broadening phenomena in chromatographic (partitioning) processes:

$$H = A + \frac{B}{\mu_x} + C\mu_x \tag{15}$$

where A, B, and C are constants for a specified separation system, and μ_x is the eluent linear flow rate. The first term, A, describes band broadening due to multiple paths in a packed column. The second term, B/μ_x, represents band broadening due to longitudinal diffusion. The third term, $C\mu_x$, describes the contribution of resistance to mass transfer to band broadening due to the equilibration of an analyte between the stationary phase and the mobile phase. The multiple path term (A) and the resistance to mass transfer term ($C\mu_x$) do not contribute to band broadening in CE, as no stationary phase is present. Therefore, under ideal CE separation conditions, the only on-column contribution to band broadening is longitudinal diffusion. The electrically driven, nearly plug flow profiles produced in CE result in inherently higher

Figure 2 Various flow profiles. (Reproduced by permission of Academic Press, Inc., from A. Weston, P.R. Brown, 'Capillary Electrophoresis', *HPLC and CE: Principles and Practice*, Academic Press, San Diego, Chapter 4, 143, 1997.)

separation efficiencies than pressure-driven LC systems with laminar (parabolic) flow profiles (Figure 2a–c).

The total plate height, H_T, for an electrophoretic peak can be described as a sum of all plate height contributions (Equation 16):

$$H_T = \frac{\sigma_{tot}^2}{L_t} \tag{16}$$

The total variance for an electrophoretic peak, σ_{tot}^2, can be considered as the sum of dispersive phenomena on a solute zone in addition to the variance due to diffusion, σ_{dif}^2 (Equation 17):

$$\sigma_{tot}^2 = \sigma_{dif}^2 + \sigma_T^2 + \sigma_{inj}^2 + \sigma_{wall}^2 \tag{17}$$

Each factor of Equation (17) will now be defined. For a more detailed theoretical discussion, the reader is referred elsewhere.[8]

Parabolic temperature gradients across the capillary, caused by undissipated Joule heating, contribute to band broadening;[9] the variance associated with this phenomenon is approximated by Equation (18)[10] for capillaries with radii between 25 and 50 μm:

$$\sigma_T^2 = \frac{r^6 E^4 C_b^2 B^2 K^2 t}{1536 D k_b^2 T^4} \tag{18}$$

where r is the capillary radius, E is the applied field strength, C_b is the concentration of the BGE, B is a constant associated with the viscosity of the BGE, K is the conductance of the BGE, t is time, D is the diffusion coefficient of the solute, k_b is the thermal conductivity of the BGE, and T is absolute temperature. Equation (18) demonstrates the importance of employing narrow-bore separation capillaries in CE.

Injection of a sample zone greater than approximately 1 mm in length[11] promotes another form of peak variance, σ_{inj}^2, as given by Equation (19):[12]

$$\sigma_{inj}^2 = \frac{l_{inj}^2}{12} \tag{19}$$

where l_{inj} is the length of the injected (approximately rectangular) sample plug.

NonGaussian peak shapes may be caused also by solute adsorption to the internal capillary wall,[13] as given by Equation (20)[14] at a specified temperature:

$$\sigma_{wall}^2 = L_t \left\{ \frac{l^2}{12 L_t} + \frac{2D}{\mu_x} + \frac{k'\mu}{(1+k')^2} \left(\frac{r^2}{4D} + \frac{2}{k_d} \right) \right\} \tag{20}$$

where l is the length of the solute zone, L_t is the total capillary length, D is the diffusion coefficient of the solute, μ_x is the linear BGE flow rate, k' is the retention factor, r is the capillary radius, and k_d is the first-order rate constant for dissociation of the solute from the capillary surface. The solute–capillary wall interactions are usually solute-specific.

Mismatched conductivity between the sample zone and the BGE can alter the electrophoretic mobilities of the corresponding ions, generating nonGaussian peak shapes. In general, if the mobility of the BGE co-ion is higher than the mobility of the solute ion, peak ''tailing'' will be observed, whereas, the converse results in peak ''fronting''. Experimentally, actual peak shapes may deviate from these generalized predictions. Using a mathematical model, Gebauer and Bocek were able to predict peak symmetry as a function of BGE concentration and pH according to peak shape diagrams.[15]

In addition, laminar flow with parabolic-shaped flow profiles may be caused by siphoning between buffer reservoirs with uneven liquid levels; laminar flow is also present in the front end of a hydrodynamically introduced sample zone. Separation efficiency can be compromised further by the finite detection window volume, or coiling of the separation capillary, with greater band broadening observed for smaller capillary radii.[16]

The dimensionless parameter of efficiency, N, is related to the following previously defined parameters (Equation 21):

$$N = \frac{L_t}{H} = \frac{\mu_{app} V}{2D} \tag{21}$$

Hence the efficiency of a band in CE is a function of applied voltage and is not dependent on capillary length at a constant voltage. Higher applied voltages will yield faster analyses times and higher separation efficiencies, assuming that the Joule heating generated is dissipated sufficiently. In addition, theory predicts that separation efficiency will be high for a large solute with a small diffusion coefficient. Theoretical efficiencies (typically greater than 10^5) are greater generally than those determined experimentally due to the aforementioned extracolumn band broadening phenomena.

Resolution, R_s, is a dimensionless parameter that accounts for both analyte migration and peak dispersion in describing the degree of separation between two analytes (Equation 22):

$$R_s = \left(\frac{1}{4}\right) \frac{\Delta\mu_{app}}{\bar{\mu}_{app}} N^{1/2} \quad (22)$$

It follows that resolution may be increased by increasing the applied voltage. However, resolution increases by the factor $V^{1/2}$, hence the Joule heat produced at higher applied voltages will dictate a practical limit. Resolution may also be increased by decreasing EOF or reversing the flow of an analyte (counter to EOF). Since the analysis time, and hence band broadening, will increase as a result, an optimization trade-off is realized. The pH of the BGE can influence resolution according to the charge and mobility of individual analytes in addition to the relative mobilities of analytes. Relative analyte mobility is described by selectivity, α, for solutes i and j (Equation 23):

$$\alpha = \frac{\mu_{app,j}}{\mu_{app,i}} \quad (23)$$

where, by definition, α is always greater than 1. Alternatively, resolution may also be calculated directly from an electropherogram according to Equation (24):

$$R_s = \frac{2(t_i - t_j)}{w_{b,i} + w_{b,j}} \quad (24)$$

where t is the migration time of the analytes and w_b is peak width at the baseline of a Gaussian peak ($w = 4\sigma$) in time units.

3 INSTRUMENTATION

3.1 Introduction

A CE system is simple in design (Figure 3). The necessary components include two electrolyte reservoirs [a source (inlet) vial and a destination (outlet) vial], a separation capillary, a high-voltage power supply, a detector, and a data acquisition device for data collection and readout. In order to perform a sample ''injection'', the inlet buffer reservoir is replaced by the sample vial, and nanoliters of sample solution are introduced into the capillary either electrokinetically or hydrodynamically. In order to perform a CE separation, the sample vial is replaced by the inlet electrolyte reservoir and the power supply is turned on. It is imperative that the electrolyte levels of the inlet and outlet vials are equalized in height in order to eliminate siphoning effects. The capillary can be liquid-cooled or air-cooled in order to dissipate Joule heating and improve the reproducibility of analyses. A variety of detectors have been employed in CE as described in section 3.5.

Figure 3 Schematic diagram of a CE instrument (not drawn to scale). (Reproduced by permission of Academic Press, Inc., from A. Weston, P.R. Brown, 'Instrumentation for Capillary Electrophoresis', *HPLC and CE: Principles and Practice*, Academic Press, San Diego, Chapter 6, 186, 1997.)

3.2 The High-voltage Power Supply

The electrical field and resulting EOF in CE are established using a direct current high-voltage power supply. In the normal polarity mode, the high-voltage cable is connected to the anode that resides in the electrolyte inlet reservoir; the ground cable is connected to the cathode that resides in the electrolyte outlet reservoir. The reversed polarity mode, where the anode and cathode of the system are switched, may be necessary for various separation mechanisms. The range of operation is typically from -30 to $+30$ kV, with a resulting operating current range of $\pm 300\,\mu$A. Access to the high-voltage electrode should be safety interlocked. Usually, a constant voltage is applied, although constant current and constant power modes can be applied as well. Field strength gradients can be applied to enhance separation performance.[17] Two 30-kV high-voltage power supplies can be used simultaneously, one connected to the anode and the other to the cathode, to apply up to 60 kV. High-voltage power supplies have also been adapted to run in the pulsed-field mode for the analysis of large molecules.[18]

3.3 The Separation Capillary

Fused silica is the most commonly used substrate for separation capillaries, providing both mechanical and chemical stability. The capillaries are coated externally with polyimide for enhanced strength and durability. A small (1-cm) section of the external polyimide coating is removed for alignment in an optical detector. Capillary IDs of 10–100 μm allow efficient dissipation of Joule heating produced during the application of high voltages. The

use of narrower bore capillaries can provide higher efficiencies, but limits the concentration sensitivity of optical detectors. Narrower bore capillaries are also susceptible to obstruction by microparticulates. Capillary lengths are typically 30–100 cm. Alternative capillary substrates and geometries have been explored briefly.[19,20] Shorter capillaries facilitate faster analysis times, but are more susceptible to sample overload. The ends of the capillary should be cleaved using a ceramic cutting tool by scoring the capillary in a single direction and pulling straight apart. This assures flat capillary edges that are advantageous especially during hydrodynamic sample introduction.

3.4 Sample Introduction

In CE, nanoliter sample volumes must be introduced efficiently and reproducibly. The two most common modes of sample introduction are hydrodynamic and electrokinetic. For hydrodynamic sample introduction, positive pressure is applied to the sample vial, negative pressure (vacuum) is applied to the outlet electrolyte vial, or the sample vial is elevated relative to the outlet reservoir in order to create a siphoning effect. Hydrodynamic sample introduction is nondiscriminatory, that is, the analyte and matrix components are introduced into the capillary in a manner that represents the original sample composition. If positive or negative pressure is applied, Equation (25) can be used to calculate the sample volume injected, V_{inj}:

$$V_{inj} = \frac{\Delta P d^4 \pi t_{inj}}{128 \eta L_t} \tag{25}$$

where ΔP is the pressure differential, d is the capillary ID, t_{inj} is the time of injection, η is the buffer viscosity, and L_t is the total capillary length. The main disadvantages of hydrodynamic sample introduction are that run-to-run reproducibilities are dependent on atmospheric pressure, the condition of the instrumentation, and the viscosity of the sample solution. Additionally, hydrodynamic sample introduction introduces a laminar flow profile to the front end of the sample zone which contributes to band broadening.

Alternatively, samples can be introduced into the capillary electrokinetically. In this mode of sample introduction, the inlet buffer reservoir is replaced by the sample vial and a high voltage is applied across the capillary for a short period of time. Both EOF and electrophoretic migration are responsible for introducing the sample into the capillary. The quantity of sample injected (Q), in moles, may be calculated according to Equation (26):

$$Q = (\mu_{ep} + \mu_{eof}) \frac{\kappa_B}{\kappa_S} E \pi r^2 C t \tag{26}$$

where μ_{ep} and μ_{eof} are the electrophoretic and electroosmotic mobilities, respectively, κ_B/κ_S is the ratio of conductivity of the buffer to the solute, E is the applied field strength, r is the internal capillary radius, C is the analyte concentration, and t is the time of injection. This method of sample introduction yields characteristically efficient peaks, but introduces sample bias as smaller, more mobile species in the sample matrix may be injected preferentially over larger, less mobile species. This in turn may lead to sample depletion over time and does not allow for accurate quantitation of sample components with different electrophoretic mobilities.

Sample stacking is a simple and universal way to increase simultaneously the peak efficiency and detection sensitivity. This is based upon conductivity differences between the solute zone and the BGE; typically, a 1 : 10 ratio of sample zone and BGE conductivities produces a Gaussian peak shape. When the separation potential is applied, the sample zone experiences a greater electrical field than the BGE owing to its lower conductance. Ions in the sample zone migrate rapidly until reaching the concentration boundary of the BGE. Positive species stack towards the front of the sample zone, negative species stack towards the back of the sample zone, and neutral species remain in the central portion of the sample zone. The higher conductivity of the BGE decreases the electrophoretic velocity of the sample species; the latter become concentrated in the narrow zone. Sample stacking has been applied in a variety of applications such as the analysis of neutral solutes in MEKC,[21] ultratrace environmental samples,[22] and DNA fragments.[23]

Trace analytes in dilute samples, especially those with complex matrices, may be concentrated up to 10 000-fold by the on-line coupling of isotachophoresis (ITP) with FSCE.[24] In ITP, analyte bands migrate at a constant velocity in an applied electrical field, positioned between a leading electrolyte and a terminating electrolyte of a discontinuous buffer system. The width of each discrete, ''stacked'' solute zone adjusts to maintain the same concentration as the leading electrolyte. Once the analyte bands reach the FSCE capillary, they migrate according to their velocity in a particular BGE and are separated. ITP preconcentration has been applied to the CE analysis of pharmaceutical samples,[25] the fractionation of human serum proteins from biological samples,[26] and chlorophenols in river and industrial wastewaters.[27]

3.5 Modes of Detection

The majority of detectors that have been applied in CE were adapted from LC. However, CE requires more stringent specifications owing to its narrower, lower volume solute zones. The CE detection method chosen for a particular application should reflect the

properties of the analyte and its sample matrix, in addition to the separation mode and BGE employed. The dynamic range, sensitivity, and selectivity of the detection method should be considered also. Detector response times of approximately 100 ms are adequate to preserve simultaneously the separation performance and detection sensitivity. For optical detection methods, on-column detection is used where a portion of the outer capillary coating is removed to create the detection window.

Many compounds possess chromophores that absorb light in the ultraviolet (UV) (190–350 nm) or visible (VIS) (350–700 nm) regions of the electromagnetic spectrum; alternatively, nonabsorbing compounds can be derivatized with UV/VIS-absorbing chromophores. As a result, the most common on-column detection mode is UV/VIS absorbance spectrophotometry. The widespread applicability of this detection mode is attributed also to its low maintenance and relatively low cost. Beer's law is observed theoretically for on-column absorbance (A) measurements (Equation 27):

$$A = \varepsilon b C \tag{27}$$

where ε is the molar absorptivity of the chromophore, b is the path length (in this case, the ID of the capillary), and C is the analyte concentration. Hence the narrow capillary dimensions limit the concentration sensitivity of this detection technique. Attempts have been made to enhance detection concentration sensitivity beyond the commonly observed range of 10^{-7}–10^{-5} M by increasing the optical path length, in "Z-cells"[28] or "bubble cells".[29] In the former, a section of the capillary is bent and absorbance is measured longitudinally down the central portion of the "Z"; in the latter, the ID of the capillary at the detection window is increased three to five times. The most common light source in UV detectors is a deuterium arc lamp, although low-pressure atomic vapor lamps can also be used. A tungsten–halogen lamp is employed commonly in the VIS range. Laser light sources have also been employed in order to enhance detection sensitivity.[30]

In a conventional, variable-wavelength UV/VIS absorbance detector, a monochrometor (single-wavelength selector containing a diffraction grating) and photon transducer (detector) are employed in a "forward" optics design. Alternatively, a polychrometer and a photodiode array (PDA) detector may be employed in a "reverse" optics design where the positions of the diffraction grating and the capillary window are reversed. The polychrometer allows the simultaneous detection of analyte absorbance at multiple wavelengths; the PDA detector can be advantageous in the confirmation of peak purity and in the identification of components in a mixture. Culbertson and Jorgenson increased the signal-to-noise ratio of a 1500-diode PDA by a factor of 85 by collecting and averaging electropherograms from individual diodes.[31] Fiber optics can be used instead of ball lenses, to collect and focus light from the capillary on to the detector. Additionally, a charge-coupled device (CCD) camera can be incorporated into the UV detection system where absorbance is recorded in two dimensions, as a function of both capillary distance and wavelength.[32]

UV/VIS absorbance detection may be applied more universally in the indirect mode.[33] A strongly UV/VIS-absorbing chromophore is added to the BGE to provide a stable background absorbance signal. Solute zones are detected as "negative" peaks owing to their displacement of the background chromophore. Typically, limits of detection are an order of magnitude poorer in the indirect mode of UV/VIS absorbance than the direct mode. To maintain a Gaussian peak shape, the electrophoretic mobilities of the analytes and the background chromophore should be comparable.

Fluorescence detectors are inherently more sensitive than UV/VIS absorbance detectors, making single-molecule detection in the VIS range a reality.[34] In CE, femtomolar limits of detection have been achieved over a wide range of path lengths (capillary diameters),[35] and linear dynamic ranges characteristically span several orders of magnitude. As molecular fluorescence is less common than UV/VIS absorbance, fluorescence detection is inherently more selective. In simple, on-column fluorescence detection, excitation radiation produced from a light source passes through a monochrometer and is focused on the capillary window. Fluorescent emission from the sample within the capillary then passes through a second monochrometer that is at a 90° angle to the excitation light path, and ultimately impinges upon a photomultiplier tube for signal detection. Intense light sources such as high-pressure mercury lamps and xenon pulse flash lamps have been applied. The use of Ar^+, He–Cd, or diode lasers as fluorescent light sources provides enhanced focusing capabilities and reduces stray light for enhanced limits of detection. However, wavelength selection can be limited with laser light sources and such high light intensities can cause photodegradation. In order to reduce the spectral background associated with the capillary walls, postcolumn[36] and sheath-flow[37] cell designs have been constructed. For further enhancement of detection limits, the fluorescent emission can be collected using a microscope objective[38] or an optical fiber. Wavelength-resolved fluorescence detection utilizing a PDA or a CCD camera has been applied to obtain qualitative analyte information without sacrificing sensitivity.[39] Time-resolved fluorescence measurements have been applied to discriminate against background Rayleigh and Raman scattering.[40] Numerous derivatization chemistries have been employed to impart fluorescence to nonfluorescent

Figure 4 ED schemes for CE: (a) porous glass coupler; (b) end-column detection; (c) optimized end-column detection. (Reproduced with permission of the American Chemical Society from A.G. Ewing, J.M. Mesaros, P.F. Gavin, *Anal. Chem.*, **66**(9), 527A–537A (1994). Copyright 1994 American Chemical Society.)

molecules. Although precolumn derivatization is most common, reports have been published utilizing postcolumn detection.[41] Fluorescent molecules employed for this purpose include *o*-phthalaldehyde (OPA), naphthalenedialdehyde (NDA), fluorescein isothiocyanate (FITC), phenylthiohydantoin (PTH), and others.[42] Indirect fluorescence detection can be employed also in CE. Analogous to indirect absorbance detection, a fluorescent ion such as quinine sulfate is added to the BGE to provide a stable background signal.[43] As an analyte molecule passes through the capillary window, the fluorescent ion in the background is displaced, and a ''negative'' analyte signal is recorded.

Electrochemical detection (ED) is cost-effective and constructed easily on a scale that is compatible to CE. In contrast to optical detection methods used in CE, capillary electrophoresis/electrochemical detection (CE/ED) does not experience a loss in sensitivity upon miniaturization, and is applicable to almost any species that can be oxidized or reduced. Three-electrode configurations are common, with a saturated calomel or Ag/AgCl reference electrode, a platinum wire auxiliary electrode, and a working electrode. Limits of detection in the 10^{-19}–10^{-17} mol range have been reported for CE/ED.[44] In the past several years, advances have been made to address the major challenge of CE/ED: the isolation of the detection system from the electrophoretic potential.

For on-line detection, the electrochemical cell current (100 fA) is isolated from the electrophoretic current (100 μA) by creating a fracture or gap between the separation portion of the capillary and the detector portion of the capillary (Figure 4a). A grounded joint constructed from porous glass,[45] porous graphite,[46] or Nafion[47] surrounds the fracture or gap and eliminates the need to place the outlet end of the capillary in a buffer reservoir. The joints can be prone to leakage and breakage, and introduce band broadening. In the end-column format, the detection electrode may be micropositioned at the end of the separation capillary (Figure 4b).[48] To facilitate the placement of the electrode, and hence the precision of analysis, the capillary end can be etched chemically to a greater ID (Figure 4c).[49] Detection limits comparable to those reported for on-line detection are approached as the outer diameter of the electrode approaches the ID of the capillary.

Amperometry is the most sensitive and most commonly employed mode of CE/ED. The current arising from the oxidation or reduction of an analyte is measured when a constant potential is applied between the reference electrode and the working electrode. Chemically modified electrodes can be utilized to facilitate slow electron transfer kinetics.[50] Fouling of the electrode surface can be controlled with pulse amperometric detection.[51] Voltammetry, measuring current as the potential applied between the reference and working electrodes is scanned, can be employed to provide qualitative analyte information.[52] Potentiometric detection utilizing ion-selective electrodes has been applied less frequently in CE.[53]

Conductivity detection is an alternative, nearly universal mode of detection in CE that has been applied to the analysis of both organic and inorganic ions.[54] Detection limits are similar to those achieved using UV/VIS absorbance detection. A pair of inert electrodes is inserted into the sides of a capillary and aligned carefully in an on-, off-, or end-column arrangement. A small, constant current is applied between the two electrodes, and the conductivity of the BGE is measured. The presence of an ion in the BGE with a differing conductivity will be detected as a solute zone. As in amperometric ED, the challenge in designing a conductivity detector is the isolation of the electrophoretic potential from the electrochemical measurement. The on-column configuration may be more challenging to construct reproducibly, but resolution can be enhanced owing to the characteristically low detector dead volume. The end-capillary configuration has the potential disadvantage of extraband broadening, but the advantage of versatility in coupling with different capillaries. The suppressed conductivity detection mode achieves lower detection limits than the nonsuppressed mode. In the former, an ion-exchange

membrane is placed at the end of the separation capillary for suppression of the conductivity of the BGE.[55]

Unique applications of CE/ED include single cell analyses[56] and the coupling of CE/ED with microdialysis for the analysis of electrochemically active species in living animals.[47] Future advances point to the further development of electrochemical array detectors for the analysis of dynamic electrochemical and separation processes.[57]

Capillary electrophoresis/mass spectrometry (CE/MS) achieves effectively two-dimensional separations, combining the high separation efficiency of CE with the ability to determine mass and structural elements of a molecule. However, interfacing CE with MS detection presents significant challenges experimentally and instrumentally. First, restrictions are placed on the BGE; those containing alkali metals, surfactants, or size-sieving polymers can be particularly problematic. Acidic buffers of low ionic strength tend to yield high detection sensitivity;[58] organic cosolvents can also be beneficial as well.[59] Second, even though mass detection limits are in the low-femtomole range, concentration detection limits are in the 10^{-5}–10^{-4} M range.[60] To circumvent this problem via CE, sample stacking, ITP, and on-line sample preconcentration can be employed. To circumvent this problem via MS, alternative interface designs, mass analyzers, and detectors can be investigated.

Three different sample ionization processes have been coupled with CE: electrospray ionization (ESI), continuous-flow fast atom bombardment (CFFAB), and matrix-assisted laser desorption/ionization (MALDI). In ESI, eluate flows from the end of the capillary through a needle held at a potential of approximately 3 kV at atmospheric pressure.[61] Solvent is evaporated quickly by the surrounding flow of a hot gas, and molecules (typically less than 100 000 Da) are ionized prior to entering the MS analyzer. In fast atom bombardment (FAB), the sample is mixed with a glycerol-based matrix (to avoid freezing of the solvent in the low-pressure conditions) and deposited directly on a probe tip. Subsequent impact with high-energy (8–10 keV) species such as xenon molecules causes desorption of the sample into the gas phase. The continuous-flow version (CFFAB) has been demonstrated for molecules smaller than 3000 Da.[62] MALDI has been almost exclusively limited to off-line analyses in CE.

Common interfaces used in CE/MS include sheath flow, sheathless flow, and liquid junction (Figure 5a–c). In the sheath-flow design, a conducting, sheathing solution is added in a 100 : 1 ratio relative to the BGE exiting the capillary.[60] This is of utility for both ESI and CFFAB that require higher liquid flow rates than that provided by EOF (microliters versus nanoliters per minute). The sheathless-flow interface at low flow rates has been used

Figure 5 Different types of CE/MS interfaces: (a) sheath flow; (b) sheathless flow; and (c) liquid junction. (Reproduced by permission of John Wiley & Sons, Inc. from J.F. Banks, *Electrophoresis*, **18**, 2255–2266 (1997).)

in conjunction with ESI for enhanced sensitivity owing to a reduced level of background ions.[63] In the liquid-junction design, the separation capillary does not enter the mass spectrometer. The outlet end of the capillary and a transfer line are positioned end-to-end, separated by a 50-μm gap.[64] A reservoir of make-up fluid surrounds the gap to promote fluid transfer.

To enhance the sensitivity of analysis in CE/MS, selected-ion monitoring (SIM) is a viable technique. In SIM, the mass spectrometer detects only a small range of mass/charge ratios as opposed to a full spectrum of mass/charge ratios. In addition to quadrupole and magnetic sector mass analyzers, time-of-flight (TOF),[65] ion-trap[66] and Fourier transform (FT) ion cyclotron mass analyzers[67] have been used to improve sensitivity marginally. The FT mode of MS can offer additional enhancement in mass resolution capabilities.

The applications of CE/MS have been plentiful. Particularly successful applications have involved the determination of impurities in peptide and protein samples[68] and the determination of drug metabolites in urine.[69] Currently, the majority of instrumentation for CE/MS is in the developmental stage. As commercial instrumentation and interfaces between CE units and mass spectrometers progress, the scope and promise of CE/MS are expected to grow.

Alternative, less common detection modes have been explored in conjunction with CE. CL detection is analogous to fluorescence detection, but the analyte molecules are excited by a chemical reaction as opposed to a high-intensity light source. Detection limits for CL are intermediate between those for UV/VIS absorbance and fluorescence detection.[70] Refractive index (RI) detectors measure changes in the RI of the BGE as analytes migrate across the capillary window. Although RI detectors are universal in application, they demonstrate low selectivity and low concentration sensitivity, and are extremely prone to interferences.[71] Radionuclide detection offers high selectivity and sensitivity in association with CE, but can introduce obvious health hazards in the laboratory. Radiation from the first-order radioactive decay of a particular nuclide (such as ^{14}C, ^{11}C, ^{99}Tc, ^{32}P, or ^{18}F) is exposed to a scintillation device that converts the radiation into photons for detection.[72] More recently, Raman spectroscopy,[73] nuclear magnetic resonance (NMR) spectroscopy,[74] and light scattering detection[75] modes have been applied in CE.

3.6 Microchip Capillary Electrophoresis

Microfabricated separation devices are miniaturized analytical systems that integrate sample introduction, electrophoretic separation, and in some instances chemical reactions, on a planar chip or wafer (Figure 6a). These postage-stamp-sized devices can manipulate picoliter volumes of liquid electrokinetically without external valves or pumps through separation channels that are millimeters in length. Higher electrical field strengths (up to 2500 V cm^{-1}) relative to conventional CE may be applied due to enhanced Joule heat dissipation. As a result, higher separation efficiencies may be achieved and analyses may be performed nearly 100 times faster (less than 1 ms in some instances) (Figure 6b). Shorter analysis times minimize longitudinal diffusion and further reduce band broadening.

Insulating substrate materials, such as glass or fused quartz, can be microfabricated as CE microchips using standard photolithographic techniques and wet-chemical etching procedures. The glass or fused-quartz wafers are annealed thermally, polished mechanically, cleaned, and sputter-coated with a metal layer, typically gold and chromium. A positive photoresist layer, approximately 1–2 μm in thickness, is then spin-coated on the surface. A photomask is applied and the wafer is exposed to UV light, producing the desired channel pattern. The exposed metal layers are removed and channels are etched using an acid bath to reveal the channel pattern. Finally, the etched wafer and cover plate are cleaned, aligned, and thermally bonded to form capillary channels. Holes are drilled to allow access to the channels. The bonding process can be repeated to eliminate defects. Further

(b) High-speed electropherogram of Rhodamine B (RB) and dichlorofluorescein (DCF) resolved in 1 ms using a separation field strength of 53 kV cm^{-1} and a separation length of 200 μm. The start time is marked with an arrow at 0 ms. (Reproduced with permission of the American Chemical Society from S.C. Jacobson, C.T. Culbertson, J.E. Daler, J.M. Ramsey, *Anal. Chem.*, **70**(16), 3476–3480 (1998). Copyright 1998 American Chemical Society.)

details of the microfabrication process are provided elsewhere.[76]

Differences between substrates should be noted. The usage of glass results in more background noise.[77] Additionally, glass fluoresces at 325 nm, whereas quartz does not fluoresce. Despite their less desirable optical properties, glass substrates are used predominantly owing to their ease of micromachining and bonding. An alternative microchip substrate is a flexible poly(dimethylsiloxane) (PDMS) silicone elastomer that is molded to a microfabricated silicon master with a raised, etched channel pattern.[78] A solution consisting of Sylard 184 and its curing agent is poured over the wafer and allowed to cure for several hours. The PDMS slab is peeled away; holes are punched to allow access to the channels. The PDMS slab is then encased in a solid, rectangular, PDMS container. PDMS offers several benefits over glass or quartz substrates. The fabrication of PDMS microchips is more time and cost efficient. In the event that channels or holes of the device become clogged, the molded PDMS slab may be removed from the solid PDMS encasement, rinsed, dried, and reused. PDMS has a low RI of 1.430, lessening the magnitude of excitation light reflected in optical detection schemes. Overall, PDMS substrates are less advantageous electrically, thermally, and optically relative to glass or fused quartz.

Prior to sample injection, the channels are flushed hydrodynamically with a buffer solution using a syringe or pipet. Platinum electrodes are placed into the inlet and outlet reservoirs for the application of voltage. Samples are injected electrokinetically; automation of sample injection enhances the reproducibility of migration times and reduces sample diffusion.

Channel geometry influences the sample introduction process, and hence the overall performance of the CE microchip. Three basic components, the straight channel, the ''T'', and the cross, can be combined to produce simple to sophisticated channel patterns. The ''double-T'' injector provides high separation efficiency.[79] In this configuration, the channel connecting the sample and sample waste reservoirs intersects perpendicularly with the separation channel (Figure 6a). Potential is applied between the sample and sample waste reservoirs. Once the slowest moving analyte has entered the intersection, the potential is switched and applied across the separation channel only. The sample plug in the intersection is swept down the separation channel and is detected. The latter is referred to as ''floating injection'' and yields sufficient relative standard deviation (RSD) values of approximately 2%. This injection technique can allow leakage and eddy mixing of the sample at the channel intersection corners, distorting field lines. For more control of sample injection volume, Jacobson et al. also introduced ''pinched injection'', where the potential is applied simultaneously across both of the channels.[80] This injection technique yields higher peak efficiencies and improved RSD values (approximately 0.3%). More sophisticated injection techniques offering finer control of injection volumes and the possibility for sample stacking have also been demonstrated.[81]

Separation efficiencies attained for the initial microfabricated devices were relatively low (less than 100 000 theoretical plates). However, separation efficiencies continue to increase with improvements in wafer design. Alternative separation channel patterns have yielded efficiency values approaching 10^6 theoretical plates; these include the serpentine[82] and synchronized cyclic CE[83] (four short channels in a square arrangement) designs. In lower resolution, higher throughput purification applications, free-flow electrophoresis has been demonstrated.[84] Several detection methods have been used in conjunction with microchip CE, including UV/VIS absorbance,[85] laser-induced fluorescence (LIF),[86] ED,[87] and MS with an ESI interface.[88] LIF detection is the most widely employed mode of detection for microfabricated devices owing to its high sensitivity and selectivity. Confocal microscopy fluorescence detection offers the possibility of single-molecule detection.[89] The coupling of microchip CE devices with MS is still in its infancy.

Several different CE separation modes have been applied using microchip CE. MEKC of coumarin dyes using sodium dodecyl sulfate (SDS) as the surfactant was demonstrated.[90] The same coumarin dyes were separated also using open-tubular capillary electrochromatography (OTCEC) with octadecyl functionalities immobilized on the channel walls.[91] The increased separation efficiencies and decreased analysis times have allowed microchip CE to be applied to the DNA sequencing, genotyping, and the amplification of DNA fragments.[92] Capillary array electrophoresis devices that use up to 12 lanes simultaneously have been applied to the detection of HLA-H variants in the diagnosis of hemochromatosis.[93] Cell lysis and polymerase chain reaction (PCR) amplification, and size-sieving of DNA fragments have been achieved on a single microchip.[94] Research has been developed also to facilitate the detection of DNA mutations on a microchip device.[95]

4 MODES OF CAPILLARY ELECTROPHORESIS

4.1 Free-solution Capillary Electrophoresis

FSCE, or CZE, is the most commonly employed mode of CE owing to its versatility; the applications of FSCE are as widely varying as the composition of

the BGEs. The separation capillary is filled with a predominantly aqueous buffer solution; additives may be incorporated into the BGE to achieve the desired selectivity and resolution of separation. The BGE chosen should demonstrate good buffering capacity and low background current to suppress Joule heating effects. The pH of the BGE can influence both the charge of the analyte and the fused-silica capillary wall according to their pK_a values. Hence the EOF in the capillary is also influenced. Some buffer additives may influence the solute – capillary wall interactions. The compatibility of FSCE with the aforementioned detection modes (section 3.5) is limited only by interferences from the BGE components. In the normal polarity mode, charged species are separated according to their respective charge-to-mass ratios in an applied electrical field. Cations migrate by coulombic attraction toward the cathode, with the cation of the lowest charge-to-mass ratio migrating fastest. Conversely, anions migrate toward the anode, with those of the lowest charge-to-mass ratio migrating fastest. At a sufficient EOF within the capillary, the coulombic attraction of the anions for the anode will be overcome, and the anions will migrate toward the cathode. Overall, the migration order in FSCE is cations (from high to low charge-to-mass), followed by neutral species (unseparated), and finally anions (from low to high charge-to-mass).

Figure 7 Migration of neutral solutes in MEKC using (a) anionic and (b) cationic pseudo-stationary phases. Separation of solutes S_1 and S_2 is achieved due to their differential partitioning into the pseudo-stationary phase. (c) The uncharged solutes are eluted within an elution window defined from t_{e0} to t_{mc}. (Reproduced by permission of John Wiley & Sons, Inc. from M.G. Khaledi, *High Performance Capillary Electrophoresis: Theory, Techniques, and Applications*, Wiley, New York, 78, 1998.)

4.2 Micellar Electrokinetic Chromatography

MEKC is one of only two modes of CE that allows the simultaneous separation of charged and neutral analytes. Since its introduction by Terabe et al. in 1984,[3] MEKC has grown dramatically to encompass hundreds of applications. The incorporation of micelles above their critical micelle concentration (CMC) in the BGE creates a pseudo-stationary phase. Differential partitioning of analytes with the micelles results in their differential migration through the capillary, and hence their separation. Since the separation mechanism involves both a partitioning process and electrophoretic migration, MEKC is considered a hybrid separation technique of FSCE and LC. However, MEKC offers several advantages over LC, including higher separation efficiencies, reduced analysis volumes and greater versatility in changing experimental parameters.

Micelles are spherical aggregates of surfactants with hydrophobic tail groups oriented toward the center of the micelle and polar head groups oriented toward the aqueous solution. The number of monomers in a micelle varies from surfactant to surfactant, and the presence of organic solvents in the separation buffer can disrupt micelle formation. The micelles will migrate through the capillary according to their apparent electrophoretic mobility, a function of both the charge-to-mass ratio of the surfactant and the EOF in the capillary. The migration of anionic micelles, such as SDS, opposes EOF in an uncoated capillary at normal system polarity. However, at sufficient EOF (pH > 6), the anionic micelles will migrate toward the cathode, past the detector (Figure 7a). The use of cationic surfactants, such as cetyltrimethylammonium bromide (CTAB), may require reversed system polarity. The cationic surfactant molecules adhere in a bilayer to negatively charged silanol groups at the capillary wall, rendering the capillary surface positively charged (Figure 7b). Nonionic and zwitterionic surfactants can also be utilized, but only in conjunction with charged surfactants. In addition to conventional surfactants, different types of organized media such as dendrimers[96] and ionic polymers[97] have been explored as psuedo-stationary phases in MEKC.

There exists a finite elution window (hence a finite peak capacity) in MEKC, between the time of migration for a neutral solute (such as methanol), t_{eo}, and the time of migration for a completely retained solute (such as the hydrophobic dye, Sudan III), t_{mc} (Figure 7c). For neutral analytes, the capacity factor, k', in MEKC is defined according to Equation (28):

$$k' = \frac{t_r - t_{e0}}{t_{e0}[1 - (t_r/t_{mc})]} \tag{28}$$

where t_r is the migration time of the solute. For charged analytes, Equation (28) must be adapted to include the time the analyte migrated in the BGE, t_0, (Equation 29):

$$k' = \frac{t_r - t_0}{t_0[1 - (t_r/t_{mc})]} \tag{29}$$

Note that as t_r approaches t_{mc}, Equations (28) and (29) are reduced to the capacity factor equation for chromatographic separations. Retention indices have been developed for MEKC, analogous to retention indices developed for gas chromatography (GC), to allow the normalization of different micellar systems.[98] The fundamental resolution equation in MEKC is given by Equation (30):

$$R = \left(\frac{N^{1/2}}{4}\right)\left(\frac{\alpha - 1}{\alpha}\right)\left(\frac{k'_2}{1 + k'_2}\right)\left(\frac{1 - (t_r/t_{mc})}{1 + (t_{e0}/t_{mc})}k'_1\right) \tag{30}$$

where N is efficiency, α is separation selectivity (Equation 23), and k'_1 and k'_2 are the capacity factors for analytes 1 and 2, respectively. Note that resolution in MEKC decreases significantly as t_r approaches t_{mc}.

The pseudo-stationary phase used in MEKC affects analyte selectivity and resolution. Currently, there are many organized media to choose from; usually, the choice is made experimentally. In order to make a more informed selection, Yang and Khaledi have established linear solvation energy relationships,[99] taking into account the relative sizes, polarizability, hydrogen bond donating properties, and hydrogen bond accepting properties of the analytes and the various surfactant molecules. Increasing the micellar concentration above the CMC in the BGE can affect the size of the elution window, but has a negligible effect on analyte selectivity. Buffer additives such as organic solvents, glucose, and urea have been added to the BGE in MEKC in order to extend the elution window, while concomitantly reducing hydrophobic interactions between analytes and micelles and altering analyte selectivities. The incorporation of a cyclodextrin (CD) into the BGE introduces shape selectivity to the MEKC separation mechanism; this is especially useful in the analysis of polycyclic aromatic hydrocarbon (PAH) structural isomers.

SDS is by far the most commonly employed surfactant in MEKC. Owing to the strong hydrogen bond donating properties of SDS, this pseudo-stationary phase is applicable to a wide variety of analytes from caffeine metabolites[100] through DNA adducts[101] to flavanoids.[102] However, SDS micelles demonstrate a practical limit in the analysis of very hydrophobic compounds such as PAHs and steroids.[103] The incorporation of CDs into SDS micellar separation solutions has been shown to increase analyte selectivity (Figure 8a–c). For particularly hydrophobic analytes, bile salts such as sodium glycodeoxycholate and sodium taurocholate are more effective than SDS.[104,105] Fluorocarbon

A*, **690**, 149–154 (1995), Copyright 1995, with permission from Elsevier Science.)

micelles, such as lithium perfluorooctane sulfonate, are also applicable to the analysis of relatively hydrophobic solutes; these pseudo-stationary phases have been applied to a limited extent in MEKC, mostly owing to a lack of availability.[106] Anionic surfactants other than SDS have been applied in MEKC including *N*-D-gluco-*N*-methylalkanamide for amino acids (AAs)[107] and (*R*)- and (*S*)-*N*-dodecoxycarbonylvaline for chiral separations.[108] Cationic surfactants, such as CTAB, have been applied in the analysis of negatively charged species such as carboxylic acids[109] and nucleic acids.[110] Nonionic and zwitterionic micelles have been applied to the separation of AAs and polypeptides.[111] Mixed micellar separation systems have received a great deal of attention recently.[112] Major advantages include expanded elution windows and alternative selectivities to accommodate the separation of complex analyte mixtures. In contrast to conventional micelles, polymeric pseudo-stationary phases, which can tolerate up to 30% organic modifier in the BGE, have been applied to particularly hydrophobic solutes such as PAHs, fullerenes, and *N*-alkylphenones.[113] The use of vesicles or the simultaneous use of oppositely charged surfactants (SDS and dodecyltrimethylammonium bromide, for instance) has been shown to enhance greatly the elution window and increase solute selectivity.[114]

4.3 Capillary Isoelectric Focusing

Traditionally, the isoelectric focusing of proteins is carried out using SGE. The adaptation of this methodology to the capillary format, first demonstrated by Hjerten and Zhu in 1985, has revealed distinct advantages.[115] cIEF involves the separation of charged analytes, usually proteins or peptides, according to their respective isoelectric points (p*I*), which is a function of their surface charge. A stable pH gradient is established and maintained in the BGE by the addition of ampholytes, species that contain both basic and acidic functionalities. Analytes will migrate through the BGE until they encounter the pH that matches their p*I*. Ideally, a linear relationship between p*I* and relative analyte mobility is established (Figure 9a and b). When the focusing of analytes is complete, the current drops to approximately one-fifth of its original value. Nonideally, solutes may interact with the internal capillary surface. The capillary surface may be treated to control such interactions and also the mobility of solutes via EOF. Covalent capillary coatings have been utilized for this purpose.[116] Dynamic capillary wall modification has been achieved in uncoated capillaries by adding methylcellulose (MC) derivatives to the BGE.[117]

After the analyte bands have been focused, they must be detected. In the absence of EOF, two schemes are commonly utilized. The first scheme, chemical mobilization, involves buffer replacement. First, the analytes are focused according to their respective p*I* values. Once the system has reached a steady state, the inlet and outlet buffer reservoirs containing a highly acidic and a highly basic solution, respectively, are replaced with buffer reservoirs containing an additional counterion (typically Na^+ in the inlet and Cl^- in the outlet). The presence of the additional ions disrupts the established steady state and the system re-establishes equilibrium to maintain electroneutrality. The analyte molecules reacquire a net charge as the pH of each zone changes. The analyte bands are separated and migrate past the detector. Concomitantly, the current in the capillary increases according to the conductivity of the BGE. Owing to an inherent anodic or cathodic ''drift'' associated with cIEF, only analytes with p*I* values between approximately 5 and 9 may be analyzed in conjunction with buffer replacement.[118] Alternatively, negative pressure and voltage may be applied simultaneously in order to mobilize the focused analyte bands toward the cathode for detection.[119] The application of voltage is necessary to maintain focused analyte bands; otherwise, laminar flow introduced hydrodynamically promotes band broadening. Additionally for the detection of focused solutes in the absence of EOF, one can visualize the entire focused solute zone within the capillary using an array detector,[120] or move the capillary itself past a stationary detector.[121] Mobilizing the analyte bands past the detector in the presence of EOF results in faster analysis times. However, the variability of EOF according to the condition of the capillary surface, as well as the pH and ionic strength of the BGE, can lead to nonlinear functions of p*I* versus analyte mobility and restrict the useful analyte p*I* range to small intervals.[122] More recent innovations involve analyte zone fraction collection with off-line MALDI/TOF/MS detection[123] and cIEF performed on microchip devices.[124]

4.4 Size-sieving Capillary Electrophoresis

The size-dependent electrophoretic separation of proteins, DNA molecules, and carbohydrates in microbore capillaries offers several advantages over conventional SGE. Reduced quantities of samples, buffers, and gel matrices are required; quantitation is facilitated by on-line detection (typically LIF or UV/VIS absorbance); the system is more amenable to automation; and faster, more efficient separations are achievable at field strengths up to $500\ V\ cm^{-1}$. Owing to the anticonvective dimensions of microbore capillaries, less rigid matrices are required to separate biomolecules in the same size range. Capillary gel electrophoresis (CGE) utilizes chemically cross-linked gels and dynamic size-sieving capillary electrophoresis (DSCE) utilizes entangled polymer

Figure 9 Electropherograms and pH gradient linearity plots for cIEF methods. (a) cIEF with chemical mobilization; (b) cIEF with hydrodynamic mobilization. Peak identification: (1) cytochrome *c*; (2) ribonuclease A; (3a–c) lentil lectin I–III; (4a, b) myoglobin I, II; (5) carbonic anhydrase I; (6) carbonic anhydrase II; (7) β-lactoglobulin; (8) trypsin inhibitor; (9) amyloglucosidase. solutions. Currently, capillary arrays of up to 100 capillaries allow the separation of biomolecules in multiple ''lanes''.[125]

The electrophoretic mobilities of biomolecules with the same charge per molecular unit are effectively independent of molecular size. Therefore, the addition of a frictional component to the BGE is necessary to achieve size-dependent separations. Two models have been used to describe the separation of biomolecules in SGE, the Ogston sieving model[126] and the reptation model.[127] The former applies to the migration of nondeformable, approximately spherical biomolecules through a porous network. For species separated according to the Ogston sieving mechanism, a linear, semilogarithmic ''Ferguson plot'' can be constructed by plotting data according to Equation (31):

$$\log \mu_T = -\log \mu_0 - K_R(T) \qquad (31)$$

where μ_T is the corresponding electrophoretic mobility of the species at that gel concentration, μ_0 is the electrophoretic mobility of the species in free solution, the slope, K_R, is the retardation coefficient, and T is the percentage gel concentration. K_R is proportional to $(r + R_g)^2$, where r is the gel fiber radius and R_g is the radius of gyration of the species. In contrast, the reptation model describes the ''snake-like'' migration of relatively larger biomolecules through the separation matrix, with electrophoretic mobilities that are inversely related to molecular size. The biased reptation model[128] and the biased reptation model with fluctuations[129] have been used to account for the concomitant stretching and conformational fluctuations of much larger biomolecules at higher field strengths.

Chemically cross-linked gels employed in CGE have well-defined, rigid pore sizes and relatively high viscosities, resulting in characteristically high separation

efficiencies. Almost exclusively, polyacrylamide gels (PAGs) have been employed in CGE with acrylamide as the monomer and *N*,*N*′-methylenebisacrylamide as the cross-linking agent.[130] Gel properties are varied by adjusting the percentage of monomer (%T) and percentage of cross-linking agent (%C) during polymerization. For mechanical stability, the PAGs are chemically bonded to the capillary wall. Serious limitations of chemically cross-linked PAGs include (i) heat sensitivity leading to bubble formation with the elimination of EOF, (ii) sample contamination by carryover between analyses, (iii) severely limited lifetimes for individual capillaries (usually less than 10 analyses per capillary), and (iv) restriction of sample introduction to electrokinetic injection.[131]

In DSCE, low-viscosity polymer solutions are employed as size-sieving matrices at concentrations above or below the entanglement threshold of the polymer. These matrices possess a highly flexible, dynamic pore structure and may be replaced between analyses to enhance run-to-run reproducibilities. Linear polyacrylamide (LPA) solutions, with zero amount of cross-linking agent, have been used.[132] The use of derivatized agarose gels requires elevated capillary temperatures (i.e. above their gelling temperature) to facilitate the loading of the separation matrix and enhance the separation mechanism.[133,134] Other polymers have been used as size-sieving matrices in DSCE, including hydroxyethylcellulose (HEC),[135] MC,[136] hydroxypropylmethylcellulose (HPMC),[137,138] and poly(ethylene oxide) (PEO).[139] The mixing of different molecular weights of the same matrix and the mixing different matrices have resulted in enhanced separation performance.[139,140] More recently, Gao and Yeung introduced the use of polyvinylpyrrolidone (PVP) in uncoated capillaries for the separation of DNA fragments.[141]

Barron et al. demonstrated that a fully entangled network is not necessary for the dynamic size-sieving separation of DNA fragments.[142] Therefore, the Ogston sieving and reptation models that involve a porous network are insufficient descriptors of the separation mechanism in DSCE. As a result, the transient entanglement coupling mechanism was proposed, whereby large biomolecules undergo interactions with multiple size-sieving polymer molecules at any one time as they migrate through the capillary, yielding size-dependent separations (Figure 10). In DSCE, lower concentrations of higher molecular weight polymers are more effective in the separation of larger biomolecules, and high concentrations of lower molecular weight polymers are more effective in the separation of smaller biomolecules.

In DSCE, EOF within the capillary must be eliminated or effectively reduced such that the size-sieving matrix does not electrophorese from the capillary. The elimination of EOF also enhances run-to-run migration reproducibilities. To this end, both covalent and dynamic capillary coatings have been utilized. Alternatively, the surface silanols on the capillary wall may be fully protonated by treatment with 0.1 M HCl.[143] For the analysis of negatively charged biomolecules, it is necessary to use reversed system polarity with the negatively charged electrode (cathode) at the capillary inlet. Other experimental variables may be optimized, including applied field strength and capillary temperature. The migration velocity of biomolecules is directly proportional to the constant, applied field strength. Additionally, potential gradients[144] and pulsed electrical fields[145] have been applied to increase the separation efficiency and resolution and decrease the analysis time in biomolecular separations. Capillary temperature gradients may also be employed in DSCE; higher temperatures result in a decrease in viscosity and an increase in dynamic pore size.[17]

Figure 10 A schematic illustration of DNA motion in a dilute HEC solution. The approximate relative sizes of HEC and small and large DNA are shown; radius of gyration (R_g) values are also given. The 118 base pair DNA fragment is unlikely to entangle strongly with the HEC in dilute solution, whereas the 9146 base pair DNA fragment has a high probability of undergoing transient entanglement coupling with many HEC molecules. When transient entanglement coupling occurs, the larger DNA molecule must drag the uncharged HEC molecules along with it during electrophoresis, decreasing its electrophoretic mobility in a size-dependent manner. (Reproduced by permission of John Wiley & Sons, Inc. from A.E. Barron, H.W. Blanch, D.S. Soane, *Electrophoresis*, **15**(5), 597–615 (1994).)

4.5 Nonaqueous Capillary Electrophoresis

Aqueous-based buffer systems have been applied predominantly in CE separations owing to the many favorable characteristics of water and its well established chemical properties. In the mid-1980s, Walbroehl and Jorgenson were the first to report the use of predominantly nonaqueous solvents in CE.[146] Ten years later, Sahota and Khaledi demonstrated the potential of nonaqueous capillary electrophoresis (NACE) and provided systematic, comparative investigations to aqueous-based systems.[147] Nonaqueous BGEs can be particularly advantageous in the analysis of relatively hydrophobic compounds. Alternative separation selectivities may be achieved with the use of nonaqueous buffers relative to their aqueous counterparts (Figure 11a and b). In general, higher applied field strengths may be employed in NACE for faster, more efficient separations of improved detectability. The selection of appropriate nonaqueous solvents should include considerations of volatility, solubility of buffer salts and additives, toxicity, reactivity, cost, and flammability. Organic solvents of various chemical and physical properties, including *N*,*N*-dimethylformamide, formamide, methanol, ethanol, and acetonitrile, have been utilized successfully in NACE.

To a first approximation, electro-osmotic mobility is directly proportional to the ratio of dielectric constant to viscosity (ε/η) of a pure solvent.[148] A majority of nonaqueous solvents possess comparatively lower ε/η ratios than water, and as a result demonstrate decreased electro-osmotic mobilities. Simultaneously, the zeta potential at the capillary wall may be affected due to a change in the pK_a of the surface silanol groups; this further reduces electro-osmotic mobilities.[149] Nonaqueous BGEs of higher ionic strengths can be applied for higher sample solubility, sample stacking, and enhanced detectability. Lower currents are generated in nonaqueous solvents so that higher field strengths can be applied without detrimental Joule heating effects; Ohm's law plots show extended linearity in nonaqueous BGEs.[147] Analogously, the electrophoretic mobilities of analytes, and hence analyte selectivities, are influenced by the characteristic ε/η ratio of the solvent.[150] Organic solvents vary in their ability to stabilize ionic species in solution and accept or donate protons. Therefore, organic solvents alter the pK_a values of acidic and basic species; generally, the pK_a values of acidic species are more affected than basic species.[151] It is important to bear in mind that in nonaqueous systems, pH values of separation media and pK_a values of solutes must be replaced by the appropriate apparent values, pH* and pK_a^*, respectively.

Several modes of detection are compatible with NACE. Direct UV/VIS absorbance detection is most commonly employed, with detection limits generally in the 10^{-5} M range.[149] Limitations exist in the application of LIF detection to NACE owing to the potential of signal quenching in lower viscosity solvents, and also changes in fluorescent excitation and emission wavelengths according to solvent polarity.[148] The use of nonaqueous separation buffers in combination with solvent evaporation in electrospray ionization mass spectrometry (ESIMS) is particularly beneficial.[152] Detection limits for NACE in conjunction with ED as low as 10^{-9} M have been reported.[149]

NACE has been applied to several classes of charged solutes, including cationic pharmaceuticals and their metabolites,[153] metal ions, organic acids,[154] peptides,[147] carboxylic acids,[150] and anionic surfactants.[155] For the separation of neutral solutes, charged

(a) Electropherogram of anions in 50 mM TRIS–acetate in water, pH 8.0; voltage, −15 kV. (b) Electropherogram of anions in 100 mM acetate in methanol, apparent pH 8.5; voltage, −12 kV. Peak identification: (T) *p*-toluenesulfonic acid; (B) benzoic acid; (G) *N*-acryloylglycine; (H) *p*-hydroxycinnamic acid; (A) *N*-acryloyl-γ-aminobutyric acid; (C) caffeic acid. (Reproduced from M. Chiari, E. Kenndler, 'Capillary Zone Electrophoresis in Organic Solvents: Separation of Anions in Methanolic Buffer Solutions', *J. Chromatogr. A*, **716**(1–2), 303–309 (1995), Copyright 1995, with permission from Elsevier Science.)

additives capable of interacting with the solutes must be employed. To this end, starburst dendrimers[96] and ionic polymers[113] have been utilized. The separation of PAHs by NACE requires charge-transfer or induced-dipole interactions provided by organic cations such as tropylium or phenyl-substituted pyrylium salts (tetrafluorborates and perchlorates).[156] Chiral separations have also been performed in NACE using CDs as the chiral selectors.[157] Such separations can be superior to their aqueous counterparts owing to the increased solubility of CDs in organic solvents and their reduced binding constants with extremely hydrophobic solutes.

4.6 Capillary Electrochromatography

CEC combines the high selectivity and versatility of LC stationary phases with the high efficiency, electrically driven flow of CE. Fused-silica capillaries are packed with stationary phase particles and the mobile phase is transported according to EOF. Neutral or charged solutes are separated on the basis of their differential partitioning interactions between the stationary phase and the mobile phase; charged solutes may also be separated according to their respective electrophoretic mobilities. In the absence of pressure-driven laminar flow, stationary phase particle diameters as small as 0.4 μm may be utilized. As a result, column efficiencies are usually an order of magnitude greater in CEC than in LC. The routine application of CEC to complex separation problems is currently limited by several factors, including the irreproducibility of EOF within the capillary, challenging column preparation, the production of Joule heat within the packed capillaries, and bubble formation within the capillary eliminating EOF. At present, it is unclear as to whether Joule heating within the capillary, inhomogeneous packing of the capillaries, or a combination of the two phenomena leads to bubble formation.

In CE, an electrical double layer forms at the solid/liquid interface of the capillary wall due to the presence of deprotonated silanol groups, producing EOF. In CEC, an electrical double layer is formed at the liquid/solid interface of each stationary phase particle. Theory dictates that EOF is independent of capillary ID if the latter is 20 times larger than the thickness of the electrical double layer.[158] However, the EOF in CEC is highly dependent on several experimental parameters, including characteristics of the capillary wall and stationary phase particles,[159] electrolyte concentration,[160] pH,[161] ionic strength, column temperature, and mobile phase organic modifier content.[162] The complex dependences of these parameters on the EOF result in the inherent irreproducibility of CEC. Additional on-column band broadening contributions exist relative to CE. Owing to the presence of a stationary phase in CEC, resistance to mass transfer and eddy diffusion are encountered in addition to longitudinal diffusion. In terms of off-column band-broadening processes, the column packing procedure and the presence of the frits can be problematic.[163] Rathore and Horvath have investigated discontinuities associated with flow velocity and electrical field strength in CEC.[164]

Column preparation in CEC, including frit formation and column packing, is considered to be an art at this time. The retaining frits are most commonly formed by the sintering of a plug of stationary phase particles, wetted with either water or potassium silicate solution,[165] or by in situ polymerization of a potassium silicate solution.[166] They must be mechanically stable and sufficiently porous, and must not promote significant solute band-broadening effects. Stationary phase particles may be packed by slurry techniques,[167] glass drawing,[168] the use of centripetal force,[169] or electrokinetic migration.[170]

Alternatively, OTCEC can be performed whereby the stationary phase is attached to the inner capillary walls or to channels of microchip devices.[91] The open-tubular format eliminates the eddy diffusion term of the van Deemter equation, but also reduces loadability and retention capabilities. OTCEC has been used in the separation of anions,[171] PAHs,[172] and proteins.[173]

A more recent innovation in CEC involves column construction via monolithic or sol–gel polymerization in situ to avoid the problems associated with inhomogeneous packing techniques and potentially problematic frit formation. For instance, *N*-isopropylacrylamide and 2-acrylamido-2-methylpropanesulfonic acid are copolymerized and cross-linked with *N*,*N*′-methyleneacrylamide.[174] Also, monolithic poly(butyl methacrylate–co-ethylene dimethacylate–co-2-acrylamido-2-methyl-1-propanesulfonic acid) capillary columns[175] have been synthesized and characterized in CEC. Sol–gel, monolithic fabricated OTCEC columns have been constructed,[176] forming a porous, high surface area layer on the capillary walls. Using an analogous in situ polymerization process, molecularly imprinted CEC columns may be fabricated. These have proven especially useful in chiral separation applications.[177]

The instrumentation employed for CEC resembles that of CE; however, buffer reservoirs may need to be pressurized in order to reduce bubble formation. Typical run conditions include the application of a potential of 10–50 kV across capillaries with dimensions of 0.5–1.5 m in length and 10–100 μm ID.[178] A detector window is created by removing a 1-cm section of the outer polyimide coating of the capillary. For in-column detection, the polyimide coating is removed from a packed portion of the capillary; for on-column detection, it is removed from an unpacked portion (Figure 12a). The former can lead to reduced sensitivity in optical detection modes

Figure 12 Packed capillary columns for electrochromatography as (a) an uncoupled and (b) a coupled system. (Reproduced from B. Behnke, E. Grom, E. Bayer, 'Evaluation of the Parameters Determining the Performance of Electrochromatography in Packed Capillary Columns', *J. Chromatogr. A*, **716**(1–2), 207–213 (1995), Copyright 1995, with permission from Elsevier Science.)

owing to background scattering from the particles; the latter can lead to the degradation of peak efficiency due to band broadening after passage through the end frit. Alternatively, a separate portion of capillary tubing containing a burned window may be coupled to the packed capillary using a Teflon® tubing sleeve (Figure 12b).[166] MS appears to be a viable detection scheme for packed CEC owing to the compatibility of mobile phase composition and flow rate (particularly for ESI interfaces) and the relatively higher sample capacities.[179]

A variety of stationary phase materials have been used in CEC to address chiral separations,[180] the analysis of pharmaceuticals,[181] and the resolution of PAH structural isomers.[182] Figure 13 shows the high-efficiency separation of 16 PAH structural isomers using CEC. Common particle diameters of stationary phase are 1.5–10 μm. The most common stationary phase material is octadecyl-derivatized silica. The choice of mobile phase not only affects analyte selectivity in CEC, but also directly influences the magnitude of EOF. Common organic modifiers in CEC for aqueous-based systems containing electrolyte include methanol, 2-propanol, and acetonitrile. Zare et al. demonstrated gradient elution CEC.[183] In this work, two capillaries were placed in different buffer reservoirs containing different mobile phase compositions. The two capillaries were connected to the separation capillary in a "T" formation. A separate power supply was connected to each mobile phase reservoir and the system was computer controlled to change the mobile phase composition as a function of time.

Figure 13 Electropherogram showing the capillary electrochromatographic separation of 16 PAHs. The column dimensions were 75 μm ID × 365 μm OD (33 cm packed length). The mobile phase consisted of 80% acetonitrile in 4 mM sodium borate solution. The applied voltage was 15 kV. Injection was performed electrokinetically at 5 kV for 5 s. PAH concentrations are approximately 10^{-6}–10^{-8} M. 5 APPLICATIONS

5.1 Amino Acids, Peptides, and Proteins

Most commonly, AA compounds are derivatized with fluorescent labels to enhance their detection in CE. In combination with LIF, detection levels into the zeptomole range have been achieved. The derivatization of charged AA functionalities alters the pK_a values and concomitantly electrophoretic mobilities; hence separation selectivity and resolution are affected. The majority of AA derivatization agents employed for detection in CE were developed originally for detection in LC.[184] These include 3-(4-carboxybenzoyl)-2-quinolinecarboxaldehyde (CBQCA), 4-(dimethylaminoazo)benzene-4′-sulfonyl (DABSYL) chloride, 9-fluorenylchloroformate (FMOC), PTH, NDA, OPA, FITC, dansyl chloride, and fluorescamine. In addition to FSCE, MEKC[185] and chiral CE[186] have been applied to the separation of AAs. Figure 14 shows an electropherogram of the MEKC separation of the 20 AAs labeled with PTH. According to the mode of separation employed, the BGE composition may vary greatly and must be optimized according to pH, percentage of organic modifier, and concentration of buffer additives.

The analysis of peptide mixtures is becoming increasingly important owing to their applications in the pharmaceutical industry and other fields. CE has proven

Figure 14 Electropherogram of PTH-labeled AAs with 25 mM phosphate buffer (pH 8.0) containing 50 mM SDS, at 27 kV applied voltage in a fused-silica capillary (70 cm × 50 μm ID). Detection by absorbance at 260 nm. (Reproduced by permission of John Wiley & Sons, Inc. from N.J. Kim, J.H. Kim, K.-J. Lee, *Electrophoresis*, **16**, 510–515 (1995).)

highly useful in the isolation, purification, protein digest mapping, and structural analysis of peptides. Several detection modes have been employed in conjunction with peptide separations in CE, including UV absorbance (both direct and indirect), LIF, ED, CL, radioactivity, and MS detection. Sample stacking, on-line preconcentration, and ITP preconcentration strategies have enhanced signal-to-noise ratios up to 1000-fold.[187]

For peptide separations in CE, temperature, capillary dimensions, applied field strength, and BGE composition should be optimized experimentally. Peptides can be separated according to differences in their terminal and side-chain pK_a values; however, specific pK_a values for peptides are rarely known. Owing to the charged functionalities of their AA constituents, the CE separation of peptides is influenced dramatically by the pH and ionic strength of the BGE. Additionally, the pH and ionic strength of the BGE alter the EOF in the capillary. The application of high ionic strength BGEs has been shown to enhance peptide separations; however, there is a practical limit due to the possibility of excessive Joule heating. Low-pH BGEs should be avoided as such conditions can cause analyte adsorption in uncoated fused-silica capillaries. In addition to the use of coated capillaries, buffer additives, such as metal ions, ion-pairing agents, and surfactants, have been employed to suppress capillary wall interactions.[188] These additives may also influence separation selectivities. The addition of organic solvents such as acetonitrile and aliphatic alcohols to the BGE alters the viscosity of the separation medium, and also the solubility and conformation of the peptides. For the enantiomeric resolution of peptides, chiral selectors such as CDs, bile salts, and chiral crown ethers have been utilized.[189] The impact of peptide hydrophobicity on separation in CE is unclear. Similarly, insufficient data exist concerning the effect of peptide secondary structure on separation in CE. Nonetheless, the *cis–trans* isomerization of peptides and the dependence of peptide secondary structure on hydrodynamic radius have been investigated.[190]

SGE is used extensively as a tool in protein chemistry. The transfer of this technology to the capillary format has offered several distinct advantages, including more rapid analyses with higher separation efficiencies, but at the same time has introduced new challenges. Interactions of structurally complex proteins with ionized silanol groups at the capillary wall can cause partial or complete denaturation of the proteins, generating spurious peaks and band broadening. Basic proteins are particularly problematic. Thus, regardless of the CE mode employed (FSCE, cIEF, or SSCE), the chemistry of the capillary surface is a critical experimental parameter. Depending on the concentration of the protein and its sample matrix, ITP preconcentration[191] or solid-phase

affinity purification[192] may be necessary. UV absorbance (190–280 nm) of peptide bonds or AA side-chain functionalities is the most common detection mode. LIF detection has been applied to a significantly lesser extent; both covalently bonded and noncovalently bound fluorescent dyes have been applied.[193] MS detection with a TOF analyzer has proven useful in the confirmation of molecular weights of proteins. Both MALDI/MS and ESIMS have been investigated; however, the former cannot be directly interfaced to the CE instrument at this time.

The strategy chosen for capillary surface modification in protein analysis should reflect the properties of the protein including its p*I* and post-translational modification chemistry. In high-pH buffers (above the p*I* for a protein), proteins are negatively charged, causing repulsion at the negatively charged wall. However, the secondary and tertiary structures of proteins are sensitive typically to pH extremes. Also, proteins have less charge diversity under such conditions, reducing the likelihood of their separation. Salts, amines (ranging in size from hydroxylamine[194] to chitosan[195]), surfactants, polyanions, and zwitterions can be added to the BGE to assist in protein separations. These additives compete for negatively charged sites at the capillary wall effectively to eliminate or reverse the direction of EOF. These additives can also form ion pairs with the proteins and alter their electrophoretic mobilities. Neutral polymers such as poly(vinyl alcohol) (PVA),[196] polyethyleneimine (PEI),[197] and cellulose derivatives[198] can be used to coat dynamically the capillary surface and nearly eliminate EOF. Figure 15(a) and (b) demonstrates the effects of a dynamic PVA coating versus a thermally immobilized PVA coating in the CE separation of five proteins. In addition, several chemistries have been proposed for the covalent modification of the capillary wall; the most frequently used covalent wall coating is polyacrylamide.[199] Alternative covalent coatings involve silanization chemistries, or the polymerization of cellulose derivatives, acrylates, and polyimines. Polymeric coatings tend to be more robust with respect to pH.[200]

A multitude of reports have appeared encompassing the separation of several classes of proteins in CE. Only a selected number of protein applications will be addressed here. FSCE has been used to separate charge variants of recombinant DNA-derived proteins,[201] conformational hemoglobin variants,[202] food proteins,[203] antigen–antibody complexes,[204] and microheterogeneous glycoproteins.[205] Lipoproteins may require the addition of surfactants or organic solvents to the BGE to enhance solubility.[206] cIEF has been used to separate monoclonal antibodies,[207] and in conjunction with immunoassays to resolve bound versus unbound antigen–antibody complexes.[208] In SDS/CGE or SDS/DSCE, proteins are denatured with 0.1% SDS and separated according to molecular weight, independent of conformation.[209] Even though this method offers advantages over the traditional sodium dodecyl sulfate/polyacrylamide gel electrophoresis (SDS/PAGE) technique, both techniques may be supplanted by MS detection in protein molecular weight determinations.

Figure 15 Effect of dynamic and permanent coating of PVA on the separation of proteins using (a) 0.05% (w/w) PVA as buffer additive and (b) thermally immobilized PVA. Sample: (1) cytochrome *c*, (2) lysozyme, (3) trypsin, (4) trypsinogen, and (5) α-chymotrypsinogen. Fused-silica capillary, 50 μm ID, 70 cm total length, 57 cm effective length; buffer, 50 mM sodium phosphate (pH 3.0), temperature, 20 °C; detection, UV absorbance at 214 nm; injection, 10 kV for 5 s; voltage, 30 kV (357 V cm^{-1}). 5.2 Nucleic Acids and Oligonucleotides

DNA molecules are negatively charged at pH values greater than approximately 4 and migrate accordingly in an applied electrical field. DNA separations are performed typically in aqueous TRIS–borate–EDTA buffer solutions, pH 8.3, to maximize solubility. In CE, the detection of DNA molecules can be achieved based on native UV absorbance at 260 nm, or by LIF. The latter enhances detection selectivity and sensitivity, but typically requires the labeling of DNA molecules with fluorescent molecules.

For the analysis of single-stranded DNA (oligonucleotides), a denaturant such as formamide or urea is added to the separation medium to prevent reannealing and secondary structure formation. The use of chemically cross-linked gel matrices in CGE offers single-base resolution,[210] but the use of low-viscosity, replaceable polymeric matrices in DSCE offers greater convenience and can provide comparable resolving power. In general, low molecular weight polymers are employed

Figure 16 Four-color M13 DNA sequencing traces analyzed from a microchip CE device. Separation was performed on a 7-cm long channel with a 100-μm twin-T injector using 4% LPA as the separation medium at 40 °C. Separation was performed with a voltage of 160 V cm^{-1} and the detector was 6.5 cm from the injector. Only 2 μg of DNA template were employed per reaction, and 1 μL of the final reaction solution (33%) was loaded on the microchip device. The run was complete in 20 min. (Reproduced with permission of the American Chemical Society from S. Liu, Y. Shi, W.W. Ja, R.A. Mathies, *Anal. Chem.*, **71**(3), 566–573 (1999). Copyright 1999 American Chemical Society.)

at high concentrations for the separation of small oligonucleotides. Capillary affinity gel electrophoresis has been applied to the separation of oligonucleotides according to size and base-specific recognition.[211]

DNA sequencing of oligonucleotides is a rapidly growing application in CE.[212–214] The Sanger dideoxy base labeling chemistries, separation mechanisms, and methodologies currently employed in CE originated in SGE. The most desirable methodology involves a four-dye labeling scheme in a single capillary and the application of a ratio-based base-calling algorithm.[215] High ''read lengths'' and fast single-base resolution separations are necessary to attain the throughput necessary to accomplish the goals of the Human Genome Project. Although LPA is the most frequently used separation matrix for DNA sequencing applications, the advantages of PEO with various molecular weight ranges has been demonstrated.[216] Several formats for the multiplexing of capillaries in conjunction with DNA sequencing have been investigated, including capillary arrays of up to 100 capillaries, sheath-flow designs, and micromachined channels. Figure 16 shows four-color

DNA sequencing utilizing DSCE on a microfabricated (microchip) device. Chang and Yeung have implemented coaxial optical fibers for fluorescence excitation with an argon ion laser and detection using a CCD camera.[139] Extension to a greater number of capillaries in an array may require the use of a charge-injection device (CID). The CID is analogous to the CCD, as a solid-state imaging device, but provides more flexibility in detection schemes and less dark current for enhanced detection sensitivity.

The separation and detection of double-stranded DNA fragments (particularly PCR products and restriction fragments) have been facilitated by the incorporation of various fluorescent dyes in the separation matrix, such as oxazole yellow (YO) (commercially available as YO-PRO-1), oxazole yellow homodimer (YOYO), thiazole orange homodimer (TOTO), and ethidium bromide. These molecules intercalate between DNA base pairs to (i) stiffen the molecules, (ii) increase their positive charge, and (iii) increase their separation resolution.[217] For the separation of DNA fragments between 1000 base pairs and 1.6 megabase pairs in length, the applied field strength can be alternated in its direction and frequency as a function of time.[218] This periodic variation of the applied field strength, or field inversion, forces the DNA molecules to reorient continuously as they migrate through the capillary; the extent of this effect is a function of the DNA fragment length and the applied electrical field. Figure 17(a) and (b) shows the dramatic enhancement of the separation of the 1-kbp DNA ladder standard using field inversion versus the use of constant field in DSCE. Using video microscopy to monitor HEC size-sieving solutions, Morris et al. found that DNA molecules alternate between compact and extended conformations as the field strength is cycled.[219]

More recently, DSCE has been applied to the separation of DNA plasmid molecules: naturally occurring circular double-stranded DNA molecules that replicate independently of the genome.[220–223] Plasmids may adopt several conformations, including positively or negatively supercoiled, open-circular (either the relaxed form or the nicked form), and linear conformations. The electrophoretic mobility of DNA plasmids is highly dependent on the separation conditions employed, such as the BGE and the applied field strength. In addition, the majority of plasmid DNA separations have been performed in the presence of DNA intercalating dyes. As a result, differences in the migration order of conformers have been reported. DNA intercalators can provide high sensitivity in conjunction with LIF detection and enhanced electrophoretic separations of double-stranded DNA fragments. However, their presence may induce undesirable structural changes in plasmid DNA molecules, including stretching and the partial unwinding

Figure 17 Comparison of field inversion CE and constant field separation. (a) Separation of the 1-kbp DNA ladder at a constant field of 81 V cm^{-1}. (b) Separation of the same sample with field inversion at 50 Hz with $E_f = 243$ V cm^{-1} and $E_b = 81$ V cm^{-1}. Conditions: 1 × TBE buffer containing 1% hydroxypropylcellulose, 10 μM ethidium bromide in a 100-μm ID coated capillary at 25 °C. Peak identification of DNA fragments in base pairs: (1) 134; (2) 154; (3) 201; (4) 220; (5) 298; (6) 344; (7) 396; (8) 506; (9) 517; (10) 1018; (11) 1636; (12) 2036; (13) 3054; (14) 4072; (15) 5090; (16) 6108; (17) 7126; (18) 8144; (19) 9162; (20) 10180; (21) 11198; (22) 12216. of the DNA double helix, and also the reduction or reversal of the supercoiling orientation.

5.3 Carbohydrates

Carbohydrates are ubiquitous to numerous mechanisms in cellular biology; their structural diversity, including branching and optical activity, reflects their unique functions. FSCE, CGE, DSCE, MEKC, CEC, and chiral CE have been applied to the analysis of carbohydrates. Their separation and detection represent a challenge in CE owing to their charge neutrality (in some cases) and lack of absorption of UV or VIS light. Therefore, as analytes in CE, they often require chemical derivatization for the introduction of detectable chromophores and charged functionalities. Additionally, carbohydrates may vary widely in structural complexity, from simple mono-, oligo-, and polysaccharides, to glycopeptides, glycoproteins, and glycolipid oligosaccharides. Sample isolation and preparation techniques should be chosen judiciously as they may influence the CE separation.

The use of alkaline borate-containing BGEs enhances the UV absorbance detection of carbohydrates at 195 nm, and simultaneously introduces negative charges to the molecules through complexation. For AA-containing carbohydrates such as glycoproteins and glycopeptides, direct UV absorbance detection may be employed. LIF detection has proven to be a valuable tool in the analysis of fluorescently labeled carbohydrates, achieving single-molecule detection levels in some instances.[224] The inherently poor sensitivity characteristic of indirect detection for carbohydrates, either UV/VIS absorbance or fluorescence, can be enhanced significantly by the use of a laser light source. Both helium–cadmium lasers (325 or 442 nm) and argon ion lasers (488 nm) have been utilized for this purpose.[225] Both electrochemical[226] and RI detection[227] of carbohydrates have been demonstrated with femtomole detection levels and linearity over three orders of magnitude of concentration. MS detection with ESI sample introduction and various mass analyzers has allowed the simultaneous structural characterization of carbohydrates.[228] MALDI/MS in conjunction with fraction isolation by CE has proven useful in the elucidation of carbohydrate branching and molecular weight;[229] future applications may involve the direct coupling of MALDI/MS with CE.

In order to enhance detection sensitivity, and in some instances improve separation selectivity, carbohydrates have been derivatized chemically. Owing to varied and/or incomplete reactivities of native hydroxyl functionalities, reductive amination followed by reaction with an amine-selective reagent, such as 2-aminopyridine, generates negatively charged analytes in neutral and alkaline pH buffers with a suitable chromophore.[230] Unfortunately, contaminating amines can be derivatized, interfering with detection. The fluorescent label 8-aminonaphthalene-1,3,6-trisulfonic acid reacts with carbohydrates by Shiff base formation.[231] Figure 18(a–c) demonstrates the effects of various fluorescent labels on the separation of a dextran sample in FSCE. CBQCA has been used in conjunction with LIF detection and PAG-filled capillaries to achieve subattomole detection levels.[232]

Being either neutral or negatively charged, the adsorption of carbohydrates to the capillary wall is less problematic than with other macromolecules such as proteins. However, capillary surface modification has been shown to increase the resolution of carbohydrates.[230] Buffer additives such as polyamines, denaturants such as urea, or ion-pairing agents such as tetrabutylammonium phosphate[233] can invoke secondary equilibria effects and consequently alter the electrophoretic mobilities of the

Figure 18 Influence of the fluorescent tag on the separation of a dextran standard with an average molecular weight of 18 300. The reagents used were (a) 2-aminopyridine, (b) 5-aminonaphthalene-2-sulfonate, and (c) 8-aminonaphthalene-1,3,6-trisulfonate. Conditions: voltage, $-500\,V\,cm^{-1}$ (10 µA); buffer, 0.1 M borate–TRIS at pH 8.65; capillary effective length, 35 cm. (Reproduced with permission of the American Chemical Society from M. Stefansson, M. Novotny, *Anal. Chem.*, **66**(7), 1134–1140 (1994). Copyright 1994 American Chemical Society.)

carbohydrate molecules. Ionic surfactants can bind to chemically derivatized celluloses,[231] and highly charged heparins can be partially neutralized by ion pairing with polycationic additives.[234] CDs can be used as buffer additives in CE to disrupt the undesirable formation of carbohydrate micelles in solution.[235]

Glycosoaminoglycan (GAG) and carboxylated or sulfated polysaccharide compounds are less difficult to separate and detect in CE owing to their inherent negatively charged sulfate groups and their absorption of UV light at 232 nm. The resolution and efficiency of these carbohydrates in FSCE and MEKC can be enhanced by suppressing EOF in the capillary with the use of an acidic BGE. In the size-sieving mode, DSCE is preferred to CGE owing to the large size of the carbohydrate molecules.[234] A highly viscous polyacrylamide solution was especially useful for the separation of the negatively charged, highly polydispersed polysaccharide hyaluronic acid.[236] Surfactant-containing BGEs can be applied in MEKC for the simultaneous separation of sulfated and nonsulfated GAGs.

The mapping, sequencing, and isomeric resolution of glycoprotein glycans have received attention recently. Varied substitution of oligosaccharide chains on the same polypeptide results in different glycoforms. Two- and three-dimensional CE separations may be necessary to resolve glycoprotein glycans.[237] Their sialic acid functionalities should be removed enzymatically prior to separation as these charged functionalities may be lost randomly during derivatization.[238] Peptides and proteins should be removed using alcohol precipitation or chromatographic techniques, or by the incorporation of surfactants in the BGE to simplify electropherograms.

5.4 Chiral Separations

Chiral enantiomers (racemates) exist as a mixture of compounds similar in structure but potentially dissimilar in function. Enzymatic reactions that occur in biological systems are stereospecific; a particular enantiomer may be preferred for maximum efficacy. Another enantiomer may be inactive or even highly toxic. Enantiomers of a chiral molecule display optical activity, differing only in the direction in which they rotate plane polarized light. In general, n chiral centers generate 2^n enantiomers. From a separation science standpoint, the resolution of chiral enantiomers can present a formidable challenge. In the past several decades, GC and, more commonly, LC have been applied to the separation of enantiomers. Since Zare et al. demonstrated the first chiral CE separation in 1985,[239] numerous reports of chiral separations have appeared in the CE literature. Chiral CE presents several advantages over chiral LC, including versatility in method development, reduced quantities of buffer volumes, chiral selectors and samples, and higher separation efficiencies. Additionally, CE may be used to measure chiral complexation constants and probe new chiral selectors for subsequent use in chromatographic applications.

Several classes of chiral selectors have been explored in CE; many of these chiral selectors were developed initially for chromatographic separation regimes. Chiral selectors differ in mechanism, hence they differ in enantioselectivity for various classes of compounds. Differential complexation of each enantiomer with a chiral selector that is dissolved in the BGE, or immobilized in a gel network or on a chromatographic support, is responsible for enantiomeric resolution. Key characteristics of CE chiral selectors include their stability and solubility in predominantly aqueous-based BGEs, low absorbance in the UV/VIS range, and multiple and varied chemical functionalities for a minimum of three noncovalent, stereospecific interactions with racemates.

Investigations have been performed in order to optimize the composition of the BGE for chiral separations. In general, the higher the binding constant between a chiral selector and an enantiomer, the lower is its required concentration in the separation system. Obviously, the pH of the BGE influences the degree of ionization of the analytes and the chiral selector, hence, the pH of the BGE influences enantioselectivity. The ionic strength of the BGE influences both the EOF and electrophoretic mobilities via the zeta potential at the capillary wall. If the ionic strength does not exceed levels that can cause additional Joule heating, sample stacking may be utilized. The presence of organic solvents in the BGE can alter binding constants and CMCs, extending the usefulness of chiral CE to more hydrophobic racemates.[240] Predominantly non-aqueous BGEs have also been used; the separation mechanisms between chiral selectors and racemates in nonaqueous buffer systems are not as well understood as in aqueous-based systems.[157] Organic cationic buffer reagents and cellulose-based buffer additives have been added to the BGE in order to reverse or suppress the EOF, thereby increasing enantiomeric resolution.

CDs and their derivatives are the most widely applicable class of chiral selectors. CDs are cyclic oligosaccharides with D-glucose units linked via α-(1,4′)-glycosidic bonds; α-, β-, and γ-CDs contain six, seven, and eight D-glucose units, respectively. The interior portion of each truncated-cone molecule is hydrophobic in nature, allowing the hydrophobic inclusion of enantiomers. Hydroxyl groups on the rim of each structure are polar in nature, promoting hydrogen bonding and dipolar interactions with enantiomers. The structure of β-CD is shown in Figure 19(a). Native CDs[241] or CDs derivatized with charged carboxyl, succinyl, and sulfate functionalities[242] have been applied. The use of derivatized CDs allows the

simultaneous separation of neutral and charged species, enhances resolution and selectivity, and alters the migration order of analytes. Electrostatic interactions may be introduced by changing the degree of ionization of the derivatized CD substituents according to the pH of the BGE. Similarly, both charged polysaccharides[243] (heparin, sulfated dextran, and sulfated chrondroitin) and neutral polysaccharides[244] (maltodextrins, maltooligosaccharides, dextrins, and dextrans) have been employed as chiral selectors in CE, albeit the binding constants of polysaccharides with racemates can be 1000-fold lower than for CDs. The macrocyclic chiral crown ether 18-crown-6-tetracarboxylic acid has been used to resolve organic and inorganic cationic enantiomers.[245] This polyether contains six oxygen atoms inside the ring for hydrogen bonding and dipolar interactions with racemates.

Armstrong et al. first demonstrated the use of macrocyclic antibiotics for chiral separations in CE.[246] The ''basket-like'' morphologies of these chiral selectors and their multitude of functionalities and stereogenic centers are responsible for their unprecedented enantioselectivities reported for hundreds of ionic and neutral racemates. Owing to their structural complexity, the optimization of experimental conditions using macrocyclic antibiotics involves a complex function of pH, ionic strength, and organic modifier content of the BGE. The chemical structure of the commonly employed multicyclic antibiotic chiral selector rifamycin B is shown in Figure 19(b). Recently, the macrocyclic alkaloid D-(+)-tubocurarine has been characterized and applied to the chiral separation of organic carboxylates.[247]

Proteins such as α_1-acid glycoprotein, bovine serum albumin (BSA), and orosomucoid have been used as chiral selectors in FSCE,[248] immobilized in a gel matrix, or covalently bonded to a solid support in CEC.[180] The secondary and tertiary structures of proteins influence their enantioselectivity, restricting the pH, ionic strength, and organic modifier content of the BGE that may be employed. Additionally, proteins can be problematic as chiral selectors owing to their strong noncovalent interactions with certain solutes and the capillary wall (reducing separation efficiencies), and also their background absorbance of UV light.

Finally, the combination of chiral CE and MEKC can generate a powerful separation tool. In chiral MEKC, natural or synthetic chiral surfactants are added to the BGE at concentrations above their CMCs. Natural, hydroxylated bile salts such as sodium cholate (Figure 19c) and its derivatives are ionized at relatively low pH, and are particularly useful for the resolution of aromatic racemates containing basic functionalities.[249] Synthetic chiral surfactants such as *N*-dodecoxycarbonylvaline (Figure 19d), with a polar AA ''head'' group and a hydrophobic ''tail'' group, are particularly useful for the separation of relatively hydrophobic enantiomers.[250] Polymer surfactants do not possess a CMC; therefore, they may be used in conjunction with higher percentages of organic modifier in the BGE, especially for hydrophobic enantiomers.

5.5 Inorganic Ions

Traditionally, ion-exchange chromatography, ion-selective electrodes, and atomic absorption spectroscopy have

been applied to the analysis of inorganic ions. More recently, FSCE with indirect UV/VIS absorbance detection has become an alternative method in the analysis of inorganic ions. Applications in the analysis of ions by indirect UV/VIS absorbance detection span several areas, including the pharmaceutical industry,[251] environmental samples,[252] and the paper industry.[253] A chromophore with the same charge and comparable electrophoretic mobility to the analyte ions is added to the BGE. Ideally, the analyte ions should exhibit minimal absorbance at the detection wavelength. The limit of detection is independent of chromophore concentration; however, chromophore concentrations of 1–10 mM are employed commonly to achieve linearity over three orders of magnitude of concentration.[254] The EOF should be in the same direction as the electrophoretic mobilities of the analytes of interest in order to reduce the time of analysis and enhance migration time reproducibilities.[255] Therefore, in the FSCE analysis of anions, a positively charged surfactant is added to the BGE in order to reverse the EOF. Analyte selectivity is influenced by the chemical properties of the surfactant and its concentration.[256]

Chromate is the most commonly employed chromophore, exhibiting absorbance from 200 to 400 nm. For enhanced detection sensitivity, the chromophore pyromellitic acid has been employed.[257] Other chromophores include naphthalene sulfates,[258] benzoate,[259] and ribonucleotides for polyphosphonates and polyphosphates.[260] Tetradecyltrimethylammonium bromide (TTAB) is the most commonly employed EOF reversal agent, but demonstrates limited detectability for bromide ion. Therefore, for samples containing bromide ion, tetradecyltrimethylammonium hydroxide has been employed.[261] The capillary walls may be dynamically or covalently coated to reverse the EOF.[262,263] Additionally, one or more co-ions may be added to the BGE for buffering purposes and to promote sample stacking.[264] Some inorganic anions such as chloride, bromide, iodide, chromate, thiocyanate, molybdate, tungstate, arsenate, nitrate, and nitrite are detectable in the low-UV region from 180 to 200 nm.[265] The direct UV/VIS absorbance detection of inorganic anions must involve a non-absorbing co-ion. For both indirect and direct UV/VIS absorbance detection of anions, limits of detection are approximately in the micrograms per liter range.

For the analysis of inorganic cations, the addition of EOF reversal agents to the BGE is not necessary. However, anionic and neutral complexing agents such as EDTA, glycolic acid, tartaric acid, citric acid, lactic acid, succinic acid, and 18-crown-6 can be added to alter analyte selectivities. Typically, the concentrations of these agents are a function of their electrophoretic mobilities and complexation constants. Imidazole is the most universal chromophore for cation analysis.[266] Direct

Figure 20 Electrophoretic separation of 22 anions and cations. Peak identification: (1) $S_2O_3^{2-}$; (2) Br^-; (3) Cl^-; (4) SO_4^{2-}; (5) NO_2^-; (6) NO_3^-; (7) WO_4^{2-}; (8) MoO_4^{2-}; (9) citrate; (10) maleate; (11) fumarate; (12) F^-; (13) HPO_4^{2-}; (14) Cs^+; (15) K^+; (16) NH_4^+; (17) HCO_3^-; (18) acetate; (19) Na^+; (20) Ca^{2+}; (21) Mg^{2+}; (22) Li^+. Conditions: indirect absorbance detection at 262 nm with peak reversal; time between injections, 80 s. (Reproduced with permission of the American Chemical Society from P. Kuban, B. Karlberg, *Anal. Chem.*, **70**(2), 360–365 (1998). Copyright 1998 American Chemical Society.)

UV/VIS absorbance detection may be used for cations after complexation with 8-hydroxyquinoline-5-sulfonic acid.[267] Quang and Khaledi developed a computer model to facilitate the multiparameter optimization of separations involving complexation agents. Their model could be used to simulate and predict the electrophoretic mobility of metal cations as a function of the pH and composition of the BGE.[268]

Anions and cations have been detected simultaneously using 4-aminopyridine as the chromophore; anions and cations approach a centrally located detection window from opposite directions of the same capillary (Figure 20).[269] In addition to direct and indirect UV/VIS absorbance, indirect fluorescence,[270] MS,[271] electrochemical,[272] and suppressed or non-suppressed conductivity[273] detection have been applied to the analysis of inorganic ions in CE. For conductivity detection, a tradeoff exists between sensitivity and symmetrical peak shape; distinct differences in conductivity but similar electrophoretic mobilities must exist for the analytes relative to the co-ion. Conductivity detection of inorganic ions can achieve relatively lower detection limits (nanograms per liter) in conjunction with sample stacking.

ABBREVIATIONS AND ACRONYMS

AA	Amino Acid
BGE	Background Electrolyte

BSA	Bovine Serum Albumin
CBQCA	3-(4-Carboxybenzoyl)-2-quinolinecarboxaldehyde
CCD	Charge-coupled Device
CD	Cyclodextrin
CE	Capillary Electrophoresis
CEC	Capillary Electrochromatography
CE/ED	Capillary Electrophoresis/Electrochemical Detection
CE/MS	Capillary Electrophoresis/Mass Spectrometry
CFFAB	Continuous-flow Fast Atom Bombardment
CGE	Capillary Gel Electrophoresis
CID	Charge-injection Device
cIEF	Capillary Isoelectric Focusing
CL	Chemiluminescence
CMC	Critical Micelle Concentration
CTAB	Cetyltrimethylammonium Bromide
CZE	Capillary Zone Electrophoresis
DABSYL	4-(Dimethylaminoazo)benzene-4′-sulfonyl
DSCE	Dynamic Size-sieving Capillary Electrophoresis
ED	Electrochemical Detection
EOF	Electro-osmotic Flow
ESI	Electrospray Ionization
ESIMS	Electrospray Ionization Mass Spectrometry
FAB	Fast Atom Bombardment
FITC	Fluorescein Isothiocyanate
FMOC	9-Fluorenylchloroformate
FSCE	Free-solution Capillary Electrophoresis
FT	Fourier Transform
GAG	Glycosoaminoglycan
GC	Gas Chromatography
HEC	Hydroxyethylcellulose
HPMC	Hydroxypropylmethylcellulose
ID	Inner Diameter
ITP	Isotachophoresis
LC	Liquid Chromatography
LIF	Laser-induced Fluorescence
LPA	Linear Polyacrylamide
MALDI	Matrix-assisted Laser Desorption/Ionization
MC	Methylcellulose
MEKC	Micellar Electrokinetic Chromatography
MS	Mass Spectrometry
NACE	Nonaqueous Capillary Electrophoresis
NDA	Naphthalenedialdehyde
NMR	Nuclear Magnetic Resonance
OPA	*o*-Phthalaldehyde
OTCEC	Open-tubular Capillary Electrochromatography
PAG	Polyacrylamide Gel
PAH	Polycyclic Aromatic Hydrocarbon
PCR	Polymerase Chain Reaction
PDA	Photodiode Array
PDMS	Poly(dimethylsiloxane)
PEI	Polyethyleneimine
PEO	Poly(ethylene oxide)
PTH	Phenylthiohydantoin
PVA	Poly(vinyl alcohol)
PVP	Polyvinylpyrrolidone
RI	Refractive Index
RSD	Relative Standard Deviation
SDS	Sodium Dodecyl Sulfate
SDS/PAGE	Sodium Dodecyl Sulfate/Polyacrylamide Gel Electrophoresis
SGE	Slab Gel Electrophoresis
SIM	Selected-ion Monitoring
SSCE	Size-sieving Capillary Electrophoresis
TOF	Time-of-flight
TOTO	Thiazole Orange Homodimer
TTAB	Tetradecyltrimethylammonium Bromide
UV	Ultraviolet
UV/VIS	Ultraviolet/Visible
VIS	Visible
YO	Oxazole Yellow
YOYO	Oxazole Yellow Homodimer

The word ''chiral'' is derived from the Greek word ''cheir'', which means hand. Chiral molecules are molecules that are related to each other in the same way that a left hand is related to a right hand. These molecules are mirror-images of each other and are nonsuperimposable. Chiral separations have been considered among the most difficult of all separations since enantiomers have identical chemical and physical properties in an achiral environment. In this chapter we will focus on techniques used in high-performance liquid chromatography (HPLC). Most chiral separations by HPLC are accomplished via direct resolution using a chiral stationary phase (CSP). In this technique a chiral resolving agent is bound or immobilized to an appropriate support to make a CSP, and the enantiomers are resolved by the formation of temporary diastereomeric complexes between the analyte and the CSP. Various types of CSPs have been developed, including ligand exchange, protein-based, carbohydrate-based, Pirkle-type, cyclodextrin-based, and macrocyclic antibiotic-based CSPs.

Ligand exchange phases are used with aqueous buffer mobile phases in which enantiomers are separated based on the differences in their charge and ionization constants. Limitations are that only ionized analytes can be separated using this technique and the copper-salt containing mobile phases used absorb in the ultraviolet (UV) region, decreasing detection sensitivity. Protein-based CSPs comprise a number of commercially available columns. These CSPs can be used in the reversed-phase mode with aqueous buffers and there are a limited number of variables to control in developing a separation method. Advantages of protein-based CSPs include low column capacity, limited solvent options and the inability to reverse the elution order of the analyte. The carbohydrate-based CSPs consist of derivatized cellulose and amylose phases and are generally used in the normal phase mode, with the exception of two derivatized phases which are conditioned for the reversed-phase mode. The main disadvantages of these phases are the limitations in pressure and solvent used since these phases are not covalently bonded but merely adsorbed on the silica. These phases may not be used with solvents of intermediate polarity, for example, methylene chloride, acetone, tetrahydrofuran, and acetonitrile. The Pirkle-type CSP typically uses nonpolar organic mobile phases such as hexane, with 2-propanol or ethanol as organic modifiers. Under these conditions, retention of the solutes decreases as the mobile phase polarity increases, following the normal phase mode behavior. The Pirkle-type columns are generally employed in separating compounds containing a π-acid or π-basic moiety, or both. The cyclodextrins can be used with either aqueous buffers or in the polar organic mode. Generally analytes separated using the cyclodextrins require formation of an inclusion complex with the cyclodextrin. Separation is most favorable when the analyte interacts with the mouth of the cyclodextrin molecule via hydrogen bonding to the functional groups present. The

macrocyclic antibiotics can be used in either the reversed-phase or the normal phase mode. Enantioselectivities in each mode have been shown to be different. Furthermore, the macrocyclic antibiotics can be derivatized to alter their selectivity. The bonded macrocyclic antibiotic CSPs resemble the protein-based CSPs in many ways. However, the macrocyclic antibiotic CSPs are more stable and have greater capacities than the protein-based CSPs. Numerous analytes are separated using this class of CSP.

1 INTRODUCTION

Chiral separations are important in many scientific disciplines such as chiral synthesis, mechanistic studies, catalysis, kinetics, biology, pharmacology, medicine, and biochemistry. The importance of stereochemistry has long been known, being first recognized more than 100 years ago by Pasteur and van't Hoff-LeBel.[1,2] In the early 1800s Pasteur achieved the first chiral resolution of a racemic mixture into optical isomers. Using no more elaborate equipment than a microscope and tweezers, he separated the ''right-handed'' crystals of ammonium tartaric acid from the ''left-handed''. The word ''chiral'' is derived from the Greek word ''cheir'', which means hand.[3] Chiral molecules are molecules that are related to each other in the same way that a left hand is related to a right hand; that is these molecules are mirror-images of each other and are nonsuperimposable (see **(1)** and **(2)**). The most common example of a chiral molecule is one that possesses a tetrahedral carbon (also known as a stereogenic center) with four different substituents. However, this is not the only requirement for a molecule to exist as chiral. Atoms other than carbon such as nitrogen, sulfur, phosphorus, etc. can also create chirality as well as molecules that lack a reflection symmetry. Structures **(3–6)** are examples of chiral molecules.

Molecules with different spatial arrangement of atoms may be classified as either diastereomers or enantiomers.[4] The term chiral and enantiomers are related in that enantiomers occur only with compounds whose molecules are chiral, that is, left- and right-handed. Diastereomers are stereoisomers which contain one or more asymmetric centers that are not enantiomers of each other. Two stereoisomers cannot be both diastereomers and enantiomers concurrently. Diastereomers have different chemical and physical properties. They can be distinguished from one another by a number of techniques that take advantage of these different properties. Enantiomers, on the other hand, have identical chemical and physical properties. The only difference is that enantiomers rotate plane-polarized light in opposite

(1)

(6)

directions and interact differently in a chiral environment. Traditionally, chiral separations have been considered among the most difficult of all separations. This is because most conventional separation techniques such as distillation, crystallization, and liquid–liquid extraction, are based on differences in chemical and physical properties of the analytes. The separation of enantiomers is a challenging problem from both theoretical and experimental approaches.

The intense interest in enantiomeric separations emerges not only from pure scientific curiosity. Government guidelines regulating the development of new drugs mandate efficient methods for the analysis and preparation of enantiomerically pure compounds. Nature's well-known ability to produce and convert chiral compounds with remarkable stereospecificity has been fascinating and led to the study of stereochemical composition of chemical compounds and their pharmaceutical importance. The effect of chiral molecules on the reaction mechanism has long been studied by spectroscopists and organic chemists. Examples of enantiomeric resolutions (resolving stereochemical composition of chiral compounds) can be found in physiological reactions. For example, catecholamines epinephrine and norepinephrine, which are synthesized in the human body mostly by the adrenal medulla, are endogenous hormones that are important in the regulatory processes such as blood pressure, metabolism, and fight-or-flight response.[5] The biochemical synthesis of catecholamines begins with an amino acid tyrosine, which is converted to L-DOPA (3-(3,4-dihydroxyphenyl)alanine). L-DOPA is then converted by L-DOPA decarboxylase, a sterospecific enzyme affecting only the L-enantiomer, to dopamine.[6] Then, another stereospecific enzymatic hydroxylation converts

dopamine into the chiral compound norepinephrine and subsequently to epinephrine by N-methylation. L-DOPA is administered to patients suffering from Parkinson disease to increase the blood level of dopamine in these patients.[6,7] The importance of the correct configuration is also evident from the fact that the naturally occurring *R*-epinephrine is at least 20 times more active than its enantiomer. Likewise, *R*-(−)-isopropyl norepinephrine is approximately 800 times more effective at the β_2 receptor as a bronchodilator than its enantiomers.[2]

1.1 General Considerations for Chromatographic Stationary Phases

Since the two forms of enantiomers have identical chemical and physical properties in an achiral environment, separating chiral compounds requires a different approach. The new approach to obtain chiral separations is to create a ''chiral environment'', which provides more specific interactions between chiral selector-chiral analyte than is obtainable in conventional techniques. Chromatographic methods such as HPLC, thin-layer chromatography (TLC), and gas–liquid chromatography (LC), offer distinct advantages over conventional separation techniques.[8] These methods show promise in moderate-scale separations, offering substantial increases in efficiency. In this chapter we will focus on techniques used in HPLC.

There are four separation modes in HPLC.[9] These include liquid–liquid chromatography, liquid–solid chromatography, size-exclusion chromatography, and ion-exchange chromatography. The most important and commonly used mode in HPLC is liquid–liquid chromatography. The support generally employed is specially treated, size distribution-controlled silica. The separation occurs due to differences in retention of various compounds on the stationary phase. The stationary phase can be divided into two large categories: partition chromatography and adsorption chromatography. In partition chromatography the stationary phase used is a liquid, whereas in adsorption chromatography a solid is utilized as a stationary phase. The use of bonded organic phases for HPLC, which will be discussed later in this chapter, has blurred this distinction between partition and adsorption chromatography.

While there are various ways to separate chiral compounds, the common denominator among the available techniques is to create a chiral environment, in which the individual enantiomers can interact differently. It is therefore necessary to employ a chiral resolving agent (commonly called chiral selector) in separating chiral compounds. The use of chiral selectors can be divided into two broad categories: techniques that involve a chiral additive in the mobile phase and techniques that use a CSP, which is immobilized either directly in the column or immobilized on an appropriate support.[10] Another possibility is indirect separation where the analyte is derivatized prior to separation with a chiral reagent to produce diastereomers, which can be separated via achiral chromatographic methods. We will focus on direct resolution of enantiomers.

1.2 General Considerations for Mobile Phase Parameters

Mobile phase selection must be given careful consideration in HPLC. The degree of chemical purity should be seriously taken into consideration since solvent contamination can cause a variety of problems ranging from sensitivity, detection, and resolution, to name but a few. Particulates present in the solvent must be removed, for example by filtration. Also, when using aqueous solvent system such as buffers, bacterial contamination must be addressed. Furthermore, dissolved gases in the solvent can lead to problems with pumps and detectors. Dissolved oxygen, in particular, can cause detection problems, resulting in nonreproducible changes in absorbance when using a UV detector at low wavelengths (210 nm).[9] Additionally, it is crucial to select a mobile phase that is compatible with the stationary phase. Highly basic or acidic solvents, for example, can attack the silica support and destroy the packing of the column.

Other considerations in selecting a mobile phase in HPLC include solubility and polarity. The mobile phase selected must be able to dissolve the analyte and not allow the analyte to precipitate in the column. For example, a sample of protein dissolved in an aqueous buffer at a pH near its isoelectric point tends to be least soluble. Selecting a suitable composition of the mobile phase depends on the type of chiral reagent employed in the separation. When a chiral counterion is used such as in ion-pair chromatography, a mobile phase of low polarity such as methylene chloride is generally used to promote ion-pair formation.[8] On the other hand, when serum albumin is used as a chiral agent, the more appropriate choices for a mobile phase are aqueous solvents with phosphate buffers.

Viscosity is another factor to address when choosing between two mobile phases of similar polarity. Lower viscosity solvent tends to cause less pressure drop in the column, resulting in a greater degree of permeability through the stationary phase.[9] The less viscous mobile phase generally results in a faster separation time. The retention of the analyte in the column also can be increased or decreased by adjusting the concentration of the counterion or by adding a modifier. Adding a polar modifier such as 1-pentanol to the mobile phase will usually result in reduced stereoselectivity.

2 CHIRAL MOBILE PHASE ADDITIVES

One approach to provide a chiral enviroment is to add a chiral reagent to the bulk mobile phase.[11,12] Interestingly, many of the compounds used to synthesize the various CSPs were originally used as chiral mobile phase additives in TLC. The separation of chiral compounds by HPLC using a chiral selector in the mobile phase is based on the transient formation of diastereomeric complexes between the chiral selector and enantiomers of the analyte. The differences in the stability of the diastereomeric complexes, their solvation in the mobile phase, or binding of the diasteromeric complexes to the solid support, lead to differences in retention time. Generally, the enantiomer that forms the weakest diastereomeric complex will elute first, whereas the more stable complex will be retained in the column longer and will elute last.

The advantages of chiral mobile phase additives with respect to CSPs are the chiral selector added to the mobile phase can be easily changed; separations are less expensive since conventional achiral stationary phases are used; and a wider variety of chiral selectors are available as mobile phase additives than are available as CSPs. From a developmental standpoint, potential chiral selectors are much more readily investigated as a mobile phase additive than as a new CSP due to the difficulty and cost involved in synthesizing a CSP. Disadvantages associated with chiral mobile phase additives include interference with detection or recovery of the analyte, as well as impurity in the chiral additive can complicate the analytical separation.

In this chapter we will mainly focus on CSPs, their properties and structure, their applications, and the mechanism of separation.

3 CHIRAL STATIONARY PHASE BASED SEPARATIONS

Most chiral separations by HPLC are accomplished by direct resolution using a CSP. In this technique a chiral resolving agent is bound or immobilized to an appropriate support to make a CSP, and the enantiomers are resolved by the formation of diastereomeric complexes between the analyte and the CSP. Various types of CSP have been developed, including ligand exchange, the protein-based, carbohydrate-based, the Pirkle-type, cyclodextrin-based, and the macrocyclic antibiotic-based CSPs. Although each CSP is able to separate a variety of enantiomers, the application of each CSP is typically limited to structurally related chiral compounds. Table 1 gives an overview of the classes of HPLC CSPs.

4 LIGAND EXCHANGE

Among the earliest reports of chiral separations by LC were based on work done by Davankov et al.[13] using ligand exchange. Davankov et al. developed the first practical approach for resolution of amino acids in LC. These types of columns are available from Phenomenex (CA, USA), J.T. Baker (NJ, USA), and Regis Technologies, Inc. (IL, USA). Davankov et al. attached a chiral bidentate ligand, for example, proline or hydroxyproline, to a support, and added Cu^{2+} to the mobile phase as shown in Figure 1. Ligand exchange is a retention mode in which enantiomers are separated based on the differences in their charge and ionization constants.[14] Only ionized analytes can be separated by use of this technique. This type of chromatography

Table 1 Classes of HPLC CSPs

Chiral selector	Approximate year introduced	Typical mobile phase	Generally required analyte features
Ligand exchange	1971	Aqueous buffers	α-Hydroxy or α-amino acids near stereogenic center; some nonaromatic
Crown ethers	1975	Perchloric acid	Primary amines near stereogenic center; some non-aromatic
Pirkle phase	1979	Nonpolar organic; 2-propanol-hexane	π-Acid or π-basic moieties for charge transfer complex; hydrogen bonding; dipole stacking near stereogenic center
Protein phases	1982	Phosphate buffer	Aromatic near stereogenic center; organic acids/bases; cationic drugs
Cyclodextrin	1982	Aqueous buffers; polar organic	Strong inclusion complex or interaction between analyte hydrophobic moiety and mouth of cyclodextrin; hydrogen bonding near stereogenic center
Cellulosic/amylosic	1983	Nonpolar organic	Aromatic
Macrocyclic antibiotics	1994	Aqueous buffers; nonpolar and polar organic	Amines, amides, acids, esters; aromatic; hydrophobic moiety

Figure 1 Structural diagram showing the interaction between the chiral selector and the analyte in the ligand exchange CSP.

involves the reversible formation of a metal complex by coordination of substrates, which act as ligands to the metal ion. Ligand exchange chromatography takes advantage of the ability of Cu^{2+} or other divalent metal ions to form diastereomeric complexes with chiral analytes. The complexes should be kinetically labile; that is, the association–dissociation time of the complexes should be faster than the chromatographic timescale. The separation of the enantiomers using this method is based on the difference in thermodynamic stabilities between the enantiomers and a divalent cation. The complex stability is highly dependent on the transition metal used. Cu^{2+}-complexes are generally more stable and are preferable for HPLC than Ni^{2+}- or Co^{2+}-complexes, which are used more prevalently in gas chromatography (GC).[15] Other racemates that can act as bidentate ligands, such as α-hydroxycarboxylic acids, can be resolved using this method. The selectivity and efficiency of this type of separation are greatly affected by pH, ionic strength of the mobile phase, and temperature.

Some of the drawbacks using the ligand-exchange approach is its limitation to chiral molecules that can coordinate selectively with the CSP. The dependence of chiral recognition on the formation of the diastereomeric complex imposes constraints on the proximity of the metal binding sites, usually either a hydroxy or an amine α to a carboxylic acid in the analyte. In addition, the copper-salt containing mobile phase absorbs in the UV region, decreasing detection sensitivity. It is interesting to note that the only commercially successful CSP for TLC is based on the ligand-exchange technique.

5 PROTEIN-BASED CHIRAL STATIONARY PHASES

Protein-based CSPs comprise a diverse and important class of CSPs for chiral separations. Within this class of CSP, there are a number of commercially available columns including α_1-acid glycoprotein (α_1-AGP), bovine serum albumin (BSA), human serum albumin, ovomucoid, and cellobiohydrolase. Protein CSPs are natural binders of small molecules and have numerous sites due to a variety of aromatic, basic, and acidic amino acids available to interact with the chiral analyte. These CSPs can be used in the reversed-phase mode and there are a limited number of variables to control in developing a separation method. Although the bonded-protein CSPs can be used to separate a wide variety of compounds, the applicability of each type of CSP is generally limited to a class of compounds and their related structures. For example, cellobiohydrolase CSP columns can most readily resolve primary amines and some secondary amines and amides whereas ovomucoid CSP is commonly employed in the separation of cyclic and secondary amines containing an aromatic group. The earlier versions of the protein-based CSP columns suffered from a lack of hardiness and longevity. They also tend to be more labile. The second generation of these columns showed improvements in stability and efficiency. Advantages of protein-based CSPs include low column capacity, limited solvent options and the inability to reverse the elution order of the analyte. The two most commonly employed protein CSPs are BSA and α_1-AGP. A summary of commercially available protein-based CSPs are listed in Table 2.[16]

5.1 Bovine Serum Albumin Chiral Stationary Phase

5.1.1 Properties and Structure

BSA is a globular protein having a molecular weight of 66 210.[17] The protein consists of 581 single chain amino acids, and 17 intrachain disulfide bridges, which connect the 34 half-cystines with the formation of 9 double loops.[18] BSA is a relatively acidic protein with an isoelectric point of 4.7. It is highly soluble in water but, like most globular proteins, it precipitates from solution at high salt concentrations. At pH 7.0 it has a net charge of −18. It exhibits hydrophobic character, and numerous examples of bindings of organic compounds to albumins have been reported.[19] Hydrophobic interaction has been shown to represent an important contribution to the total affinity of organic ligand to BSA. However, other

Table 2 Commercially available protein-based CSPs

Protein	Preferred analytes
BSA	Aromatic acids and anionic compounds
Human serum albumin	Aromatic acids and anionic compounds
α_1-AGP	Cyclic and secondary amines with aromatic group; some acids and neutral compounds
Ovomucoid	Cyclic and secondary amines with aromatic group; some acids and neutral compounds
Cellobiohydrolase	Primary amines and secondary amines; amides

interactions such as electrostatic interactions, hydrogen bonding, and charge-transfer contribute to the total affinity as well.

The first observation of the enantioselective properties of an albumin was made in 1958 by McMenamy and Oncley,[20] who demonstrated that the affinity for L-tryptophan exceeded that of D-tryptophan by a factor of 100 in a radioisotope labeling experiment and using a dialysis technique. This finding was later confirmed in 1973 by Stewart and Doherty when they demonstrated in an affinity chromatography on BSA immobilized to Sepharose that the D-enantiomer eluted under the conditions where L-enantiomer was retained.[21] Since then there have been extensive investigations of the chromatographic behavior of various racemic compounds under different mobile phase conditions. The BSA-silica columns for HPLC were introduced commercially in 1983.[22]

5.1.2 Applications

The mobile phases generally used in BSA columns are aqueous buffers with a limited pH range, mixed with organic modifiers such as 1-propanol. Retention and enantioselectivity properties on the BSA columns can be changed by varying parameters such as pH, ionic strength of the mobile phase, and temperature.[23] Various N-acylamino acids, amines, aromatic amino acids, sulfoxides and sulfoximine derivatives and related compounds, coumarin derivatives, and benzodiazepine derivatives have been shown to enantioresolve on BSA columns. The binding properties of BSA are highly dependent on the aqueous buffer system employed. This is partly due to the protein itself, that is, the overall charge and the conformation.[23] Consequently, it is possible to optimize enantioresolution by a proper selection of mobile phase parameters.

5.2 α_1-Acid Glycoprotein Chiral Stationary Phase

5.2.1 Properties and Structure

Human α_1-AGP has a molecular weight of approximately 41 000.[24,25] It is a single 181-amino acid peptide chain with five carbohydrate units, containing sialic acid, hexosamine, and neutral hexoses. The peptide chain comprises 55% of the molecular weight. α_1-AGP contains two cystine disulfide cross-linkages, which connect residues 5 and 147 and residues 72 and 164. In phosphate buffer, the glycoprotein has an isoelectric point of 2.7. Stability studies indicate that α_1-AGP column is very stable.[25] It can be used at elevated temperatures (25–80 °C), and can tolerate organic solvents such as pure 2-propanol. The columns also may be used over a wide pH range without denaturation. Storage of the columns can be done in a water–2-propanol mixture for 12 months with approximately 10% reduction in column retention characteristics.[25]

α_1-AGP column can be prepared by immobilization of the human plasma AGP on silica particles. The preparation is based on bonding the protein to diethylaminoethyl silica followed by a cross-linking procedure.[26] The resulting enamines from the cross-linking process are reduced to secondary amines with cyanoborohydride. The α_1-AGP column is commercially available under the trade name EnantioPac (LKB Products, Bromma, Sweden). Many of the advantages of the EnantioPac columns are associated with the reversed-phase mode of the column, which allows for direct injections as well as better regulation of retention and selectivity. Additionally, many basic and acidic drug substances without derivatization can be enantioresolved using the EnantioPac column. A second generation AGP column such as Chiral-AGP, on the other hand, uses covalent linkages to attach the protein to the silica support.[27,28] Chiral-AGP columns are thus more stable and resistant to hydrolytic attack. Chiral-AGP columns contain 5 μm silica particles instead of 10 μm as in EnantioPac, which gives Chiral-AGP columns a smaller pore volume and greater surface area, adding to their mechanical stability. Bonding capacity of the chiral phase as well as loading capacity of the solute are directly dependent on the amount of protein bound to the silica particles, which in turn depends on the bonding technique and the surface area of the silica support.

5.2.2 Applications

α_1-AGP CSP columns have wide application for the direct separation of many classes of pharmaceutical compounds, as well as amines, acids, and nonprotolytic compounds.[26,29] They are often used in the determination of enantiomers at low concentrations in biological fluids such as plasma and urine.[30,31] Concentration as low as 2 nmol L^{-1} plasma has been detected using a Chiral-AGP column and fluorescence detection. Enantioresolved acidic drugs on AGP columns include ibuprofen, ketoprofen, and naproxen. Basic drugs such as disopyramide, tropicamide, atropine, and homatropine have also been resolved on AGP columns.[32,33] In addition, AGP columns have been shown to baseline-resolve various other compounds including alprenolol, atenolol, ephedrine, and warfarin.

Concentration and properties of modifiers in the aqueous mobile phase play an important role in retention and selectivity of the solutes on AGP CSPs. Retention and enantioselectivity are found to decrease with increasing concentration of uncharged organic modifiers such as methanol, ethanol, 2-propanol, and acetonitrile.[27] This trend is not universal, however. For example, in the cases of mephenytoin and methylphenobarbital, chiral

resolution can be improved by adding uncharged modifier such as 2-propanol to the mobile phase. Enantioresolution of tertiary amines such as mepivacaine and bupivacaine, on the other hand, are not affected by the addition of organic modifier. Adding up to 8% propanol to the mobile phase results in no change in chiral resolution although the retention of these solutes decreases significantly under these conditions.[26]

Solute retention is generally found to increase when a modifier with the opposite charge is added to the solutes. Additions of same charge modifiers to the solutes tend to decrease retention time. The enantiomers of propiomazine, a fenthiazin derivative, which could not be resolved on an α_1-AGP column when using phosphate buffer at pH 7.55 as a mobile phase, was baseline resolved with a longer retention time upon adding 1 mM *N*,*N*-dimethyloctylamine (DMOA) to the mobile phase.[34] The changes observed in the selectivity are believed to result from the changes in α_1-AGP conformations, which in turn result from pH changes in the mobile phase. Changes in pH have been found to affect retention and selectivity for basic, acidic, and nonprotolytic compounds. While the separation of the weakly acidic hexobarbital and basic metoprolol increases with increasing mobile phase pH, enantioselectivity of 2-phenoxypropionic acid (pK_a 4.6) decreases at higher pHs.[31] Retention and enantioselectivity are also influenced by column temperature. Generally, retention, resolution, and separation factors decrease with increasing temperature. Separation efficiency, on the other hand, usually increases at higher temperatures.

5.2.3 Separation Mechanism

Although a great deal is known about the scientific basis of separation, that is, differences in binding between proteins and drug enantiomers, the mechanisms for enantiorecognition are not well understood. It is known that the native conformation of a protein can be changed by varying pH and adding organic modifier. The α_1-AGP molecule is believed to remain flexible in the column even after bonding with silica support. Hence, the addition of modifiers to the mobile phase is thought to affect the AGP molecule, inducing different binding properties.[26,31]

6 CARBOHYDRATE-BASED PHASES

Cellulose and amylose are among the most common natural polymers of this class of CSP. They are abundant in nature. In their native state, cellulose and amylose are poor chiral selectors. Improved chromatography and enantioselectivity of these chiral selectors can be achieved by derivatizing their hydroxyl groups with aromatic moieties through ester or carbamate linkages to decrease bulk polarity and provide additional interaction between the CSP and the solute.[35] The initial work on functionalized cellulose-based CSP was investigated in Europe, but it was Daicel, Ltd. (Tokyo, Japan) who commercialized a series of cellulose and amylose CSP.[16] A number of these commercialized stationary phases are shown in **(7–16)**. Structures **(7–10)** are derivatives of cellulosic carbamate CSPs. Structures **(11–14)** are derivatives of cellulosic ester CSPs. Structures **(15)** and **(16)** are coated CSPs consisting of derivatives of amylose. The 3,5-dimethylphenyl derivatives are the most widely used cellulose-based CSP (ChiraCel OD, Daicel) and amylose-based CSP (ChiraCel AD, Daicel), respectively.[16] Presently, there are nine cellulose derivative-based columns and two amylose-derivative CSPs produced by Daicel, Ltd. These CSPs are generally used in the normal phase mode, with the exception of two types which are conditioned for the reversed-phase mode. The molecular weight of a cellulose derivative affects chiral recognition and column efficiency. Cellulose and amylose columns have good capacity in the normal phase mode and are often used in the preparative-scale separations.[35]

Derivatized cellulose and amylose are immobilized on a silica support. Mobile phases commonly employed are hexane: 2-propanol mixtures at various concentrations and occasionally more polar alcohols, such as methanol or ethanol, as well as aqueous-alcohol mixtures. These phases may not be used with solvents of intermediate polarity, for example, methylene chloride, acetone, tetrahydrofuran, and acetonitrile (over 1%). The main disadvantages of these phases are the limitations in

pressure and solvent used because these phases are not covalently bonded but merely adsorbed on the silica.

6.1 Cellulose- and Amylose-based Chiral Stationary Phases

6.1.1 Properties and Structures

Cellulose and amylose are naturally occurring polymers. They have highly organized structures, consisting of hydrogen-bonded chains of 1,4-linked D-(+)-glucose units. The glucose units on amylose are the same as the cyclodextrins and are connected via 1,4-β-linkages. However, the linkages in cellulose are 1,4-α-linkages.[12] Cellulosic and amylosic phases have been used extensively for chiral separations. The most frequently used cellulosic phase, in pure polymer form, is cellulose triacetate, which is commercially known as microcrystalline cellulose triacetate (MCA) (Daicel Chemical Industries, Ltd., Tokyo, Japan).[35] Cellulose triacetate is the product of heterogenous acetylation of microcrystalline cellulose.[17] Various cellulose ester derivatives on a silica gel support as HPLC columns are also commercially available (Daicel Chemical Industries, Ltd.). These columns appear to have good stability; however, because these chiral polymers are not attached covalently to the silica support, but are coated on silanized wide pore silica particles, caution must be taken in selecting mobile phase solvents.[36,37] Mobile phases such as hexane–2-propanol and alcohols can be used in these columns. The columns should be stored in hexane at low temperature (~4 °C).[16]

6.1.2 Applications

Cellulosic and amylosic phases have been successful in resolving structurally diverse compounds. MCA columns can be used to enantioresolve polar compounds such as amines, amides, imides, esters, and ketones.[38] Chiral selectivity seems to improve with a phenyl or a cycloalkyl group near the chiral center of the solute. Nonpolar solutes can also be separated in MCA columns, however, charged or dissociated compounds cannot be retained on these columns. Ethanol and methanol are the mobile phases generally used with these columns. The disadvantages of MCA columns include low efficiency and poor reproducibility. Additionally, a slow flow rate must be used with these columns. The Daicel columns are used for the separation of aromatic hydrocarbons with hydroxyl groups, carbonyls, sulfoxides, barbiturates, and β-blockers.[39,40]

6.1.3 Separation Mechanism

The chiral recognition sites on these carbohydrate-based CSPs are thought to be channels or grooves in the polymer matrix. The analytes are probably included in these grooves. This is evident by the enhanced enantiorecognition observed for many solutes when the steric bulk of the alcohol modifier is added to the mobile phase.[41,42] Chiral recognition appears to require the presence of an aromatic ring, for $\pi-\pi$ interactions, as well as polar sites of unsaturation and hydrogen bonding functionalities. Although the mechanism of separation by cellulose esters and carbamates is unclear, it is believed that chiral interactions result from the ester and urethane linkages.

7 PIRKLE CHIRAL STATIONARY PHASES

The first commercially available and successful CSP was developed by William Pirkle, an organic chemist with experience in chiral synthesis. The first generation of the ''Pirkle phases'', named after its creator, was introduced for LC in 1979.[43] The first generation Pirkle phase was based on the *N*-3,5-dinitrobenzoyl (DNB) moiety, which was immobilized on a silica support. Pirkle then introduced the concept that if a particular chiral selector is able to resolve certain analytes, it is more likely that a similar chiral selector to the original chiral selector could also be used to separate the analytes. Following this notion, a second generation of Pirkle phases, which were based on N-(2-naphthyl)-α-amino acids, was made.[44] Since these CSPs are produced synthetically, the stationary phase is often available in either absolute configuration.

7.1 Properties, Structures, and Applications

Using the above concept, Pirkle developed two commercially successful CSPs which are shown in **(17)** and **(18)**.[45] These phases consisted of N-(3,5-DNB) phenylglycine ionically **(17)** or covalently **(18)** attached to aminopropyl silica. These first Pirkle phases were very successful at enantioresolving compounds containing naphthyl moieties near the stereogenic center. Other phases based upon the DNB moiety were later developed **(19–21)**.[46] These included derivatives of leucine, ionically and covalently linked to an aminopropyl silica support. Since the DNB moiety is a π-acceptor, analytes for these CSPs should possess a π-donor group such as an aromatic ring with an alkyl, ether or amino substituent. These DNB phases have been successful at resolving a large number of compounds such as π-donor-substituted amines, alcohols, amino alcohols, and sulfoxides. While the covalently bonded version of these columns can be used with relatively polar mobile phases, the enantioselectivity and stability are much greater when using normal phase solvents. A second generation of Pirkle phases, which were based on N-(2-naphthyl)-α-amino acids were synthesized, providing reciprocity to the first DNB phases.[44] The

N-(2-naphthyl)-α-amino acids phases are π-donors, therefore analytes for these CSPs should possess a π-acceptor group. These columns showed selectivity toward analytes containing a 3,5-DNB group, such as 3,5-dinitrophenyl carbamates, ureas of chiral alcohols, and amines.

(17)

(18)

(19)

(20)

(21)

The most recent addition to the Pirkle phases is the commercial column marketed as the Whelk-O-1 phase (see **(22)**). The phase contains a chiral selector with a wedge-like chiral surface, with one edge containing a 3,5-DNB π-acidic moiety and the other edge comprising the π-basic tetrahydrophenanthrene ring system.[1,47] The two edges are linked together by the amide linkages. The presence of both the π-acid and π-basic, as well as the amide linkages, offers rigidity, and greater versatility than any other Pirkle phases. The Whelk-O-1 phase contains dipole stacking and hydrogen-bonding interaction sites, and imposes fewer structural constraints of the solutes and the mobile phase conditions. Because this chiral selector is small, it also promotes high bonded ligand densities in the stationary phase. This feature, coupled with the high enantioselectivity achieved with the phase, allows the Whelk-O-1 phase to be used in the preparative-scale separations.[1] Additionally, the chiral selector can interact with either the (*R*–*R*) or the (*S*–*S*) configuration of the solutes, giving the possibility of changing the elution order. This CSP has been shown to enantioresolve naproxen, warfarin, and its *p*-chloro analog, under the reversed-phase mode and nonaqueous reversed-phase condition.

(22)

The mobile phases typically used with the Pirkle phases are the nonpolar organic mobile phases such as hexane, with 2-propanol or ethanol as organic modifiers. Under these conditions, retention of the solutes decreases as the mobile phase polarity increases, following the normal phase mode behavior. Since the mobile phase only weakly interacts with the CSP, and can be easily displaced by the solutes, specific enantiomeric interactions are promoted. The Pirkle phases are commonly used in the normal phase mode, although some have been used in the reversed-phase mode.

7.2 Separation Mechanism

Of all the commercially available CSPs for HPLC, the chiral recognition mechanism for the Pirkle phases is perhaps the best understood. Enantiorecognition on the Pirkle phases is believed to depend on complementary interactions between the chiral selector and the solutes.[44,47] The interactions involved are thought to include dipole–dipole interactions, π–π, hydrogen bonding, and steric hindrance as shown in Figure 2. These interactions contribute to the overall stability of the diastereomeric complexes formed between the individual enantiomer and the chiral selector on the stationary phase. The π–π interaction arises through the association of aromatic systems with complementary electron-withdrawing and electron-donating substituents

Figure 2 A schematic diagram showing enantiorecognition in the Pirkle phase due to hydrogen binding, dipole and charge-transfer interactions, and steric hindrance.

such as the nitro and alkyl groups, respectively. The aromatic system deficient in electrons is referred to as π-acid, in contrast to the electron-rich system, which is called π-base. In order to promote and enhance chiral recognition, functional groups are often introduced into the solute through achiral derivatization. The amines may be derivatized with 3,5-DNB chloride to create a π-acid aromatic group to the solute, thereby enhancing a diastereomeric complexation with a π-basic, (*R*)-*N*-(2-naphthyl)-alanine, chiral selector in the stationary phase.[44] Also, derivatizing the solute may have an additional advantage of increasing solute solubility.

It appears that three unique interactions from the stereogenic centers of the solutes and the chiral ligand in the stationary phase are necessary for enantiorecognition. This model describing three unique interactions is called the ''3-point interaction model''. It was first proposed by Dalgliesh.[48] Pirkle had recently restated the ''3-point rule'' as ''chiral recognition requires a minimum of three simultaneous interactions between the CSP and at least one of the enantiomers, with at least one of the interactions being stereochemically dependent''.[49] While no simple model can explain all the observations of chiral recognition, the three-point attachment model has greatly aided our understanding of the chiral recognition process.

8 CYCLODEXTRIN CHIRAL STATIONARY PHASES

Another general strategy to obtain optical resolutions employs the inclusion of the analyte into a chiral cavity. This strategy was first introduced by Dotsevi et al.[50] who used a crown ether bound to silica gel. Although the chiral crown ether phases were commercialized, for example, Diacel Crown-Pak, the majority of inclusion-based separations utilized bound cyclodextrin CSPs. Cyclodextrin CSPs immobilize the cyclodextrins to a solid support in such a way that the cyclodextrin is free to interact with solutes in solution. One of the earlier uses of cyclodextrins was as mobile phase modifiers in TLC.[51,52] Immobilizing cyclodextrin on a solid support yields several advantages over its use as a mobile phase modifier. For example, the solubility of β-cyclodextrin in the mobile phase is fairly low, and the efficiency obtained is often poor. Polymerized cyclodextrin gels were initially used as stationary phases in column chromatography but with limited success.[53,54] The use of cyclodextrins in HPLC was introduced when Fujimura et al.[55] and Kawagucki et al.[56] developed a method to attach different cyclodextrins to silica gel via ethylene diamine linkages. Unfortunately, these phases were hydrolytically unstable and unsuitable for commercialization. A new cyclodextrin packing, which contained no nitrogen linkages, was later introduced by Armstrong.[57] The new columns were thought to be more widely useful and commercially feasible. The nitrogen linkages were replaced by a 6–10 atom spacer. The linkages and the cyclodextrins were hydrolytically stable, and the stationary phases had increased loading and efficiency. This stable cyclodextrin-bonded phase is sold commercially under the trade name Cyclobond (Advanced Separation Technologies, Whippany, New Jersey). This stationary phase was the first chiral CSP to be developed for use in the reversed-phase mode and has been shown to successfully resolve diverse isomers formerly thought to be difficult to separate.[58–60]

8.1 Properties and Structures

Cyclodextrins are cyclic oligosaccharides naturally formed by the action of *Bacillus macerans* on starch.[61,62] They can also be produced by use of the enzyme cyclodextrin transglycosylase from starch.[63] There have been several procedures used to control the ratios of cyclodextrins produced. One is the addition of a substance to the reaction mixture to favor one form of cyclodextrin over another. For instance, the addition of 1-decanol and 1-nonanol favorably induces the formation of α-cyclodextrin.[64] In the presence of hexane or toluene, on the other hand, β-cyclodextrin is more strongly promoted. Both α- and β-cyclodextrins are simultaneously produced in the presence of 1-heptanol.[61,64] The native cyclodextrins contain 6 to 12 glucose units, which are connected to each other by α-(1,4) linkages. There are three commercially available cyclodextrin homologs: α-cyclodextrin (cyclohexamolyose), β-cyclodextrin (cycloheptamylose), and γ-cyclodextrin (cyclootamylose) as shown in **(23–25)**, respectively. The larger cyclodextrin homologs must be individually produced and isolated.

The Greek letter preceding the name of the cyclodextrin designates the number of glucose subunits: $\alpha = 6$, $\beta = 7$, and $\gamma = 8$. Each glucose unit on the cyclodextrin is chiral. Cyclodextrins are toroidal in shape with

(23)

(24)

(25)

a relatively hydrophobic internal cavity. The 2-hydroxyl groups at the rim of the cyclodextrin cavity project in a clockwise direction. The cyclodextrins exterior is relatively hydrophilic due to the presence of the primary and secondary hydroxyl groups. The primary hydroxyl group on C-6 is free to rotate and can partially block the cyclodextrin cavity at the narrow end. The ability of cyclodextrins to form inclusion complexes with a variety of guest molecules and ions makes the cyclodextrins particulary useful for chiral separations (Figure 3).[65]

The cyclodextrins have a number of chemical and physical properties in common. Among these properties are:

Figure 3 A diagram depicting a hydrophobic inclusion complex between a cyclodextrin cavity and a chiral analyte.

cyclodextrins are nonreducing; glucose is the only product of acid hydrolysis; molecular weights are always integral numbers of 162.1, the value for glucose; cyclodextrins are nontoxic; cyclodextrins do not appreciably absorb UV or visible light. The cyclodextrin molecules as a whole are hydrophilic making these CSPs completely compatible with aqueous mobile phases. Since cyclodextrin CSPs are compatible with aqueous mobile phases, method development is aided by the use of buffers and organic modifiers in adjusting column selectivity.

8.2 Applications

The most commonly used cyclodextrin in HPLC has been the native β-cyclodextrin **(24)**. A variety of water soluble–insoluble compounds can fit into the hydrophobic cavity, forming reversible host–guest inclusion complexes.[66] It is well known that molecules possessing an aromatic group such as naphthyl or biphenyl in close proximity to the stereogenic center are particularly amenable for separation.[63] The β-cyclodextrin column has shown excellent selectivity for amino acid derivatives. For example, the native β-cyclodextrin phase has been used to resolve a variety of racemates including dansylamino acids, β-naphthyl ester derivatives of amino acids, and β-naphthylamide. It is thought that underivatized amino acids are perhaps too small to bind tightly to the cyclodextrin cavity, and subsequently cannot be enantioresolved. When a dansyl group is incorporated in the amino acid, however, strong inclusion complexes between the cyclodextrin and the derivatized amino acid can be formed, and baseline resolution is achieved. Either the carboxyl group or the amino group on the amino acid can be derivatized. Derivatization of both groups appears to result in reduced chiral recognition. Enantiomeric derivatives of ferrocene, ruthenocene, and osmocene, as well as several racemic and diastereomeric 2,2-binaphthyldiyl crown ethers, have also been successfully resolved on the β-cyclodextrin phase.[67,68] It should be noted that although the crown ethers do not contain a chiral carbon, they still exist as enantiomers because of the staggered position of adjacent naphthyl rings.[68]

α-Cyclodextrin is suitable for separating small molecules such as tryptophan, phenylalanine, tyrosine, and their analogs. γ-Cyclodextrin has been used for the separation of di- and tripeptides.

Cyclodextrin-bonded phases provide a rapid and specific technique for the pharmacological evaluation of racemic drugs. Chiral drugs such as ketoprofen, mephenytoin, chlorpheniramine, and the barbiturates mephobarbital and hexobarbital, have been separated by the cyclodextrin column.[69] Many diastereomers, geometric isomers, and epimers, can be resolved using cyclodextrin phases as well. For example, *cis*- and *trans*-benzo[*a*]pyrene were completely separated on a γ-cyclodextrin column. In addition, cyclodextrin phases are of great utility in enantioresolving structural isomers, such as the ortho-, meta-, and para-isomers of nitroaniline, xylene, cresols, nitrophenols, and substituted benzoic acids.[70] An extremely sensitive test of optical purity can be achieved with the cyclodextrin columns. Detection of as little as 0.2% of one enantiomer in a racemic mixture has been shown to be feasible using the cyclodextrin column.[63]

Limitations with the selectivity of the native cyclodextrins led to the development of various functionalized cyclodextrin-based stationary phases. These derivatized cyclodextrin phases include acetylated, sulfated, 2-hydroxypropyl, 3,5-dimethylphenylcarbamoylated, and 1-naphthylethylcarbamoylated cyclodextrin.[1,16] Since each of the glucose molecules on a cyclodextrin provides three hydroxyl groups to which a substituent may be attached, there are multiple sites on the cyclodextrin available for derivatization. Typically, each β-cyclodextrin, which contains 21 hydroxyl groups, has a degree of substitution ranging from 3 to 10 derivatized groups per cyclodextrin molecule. The groups on these functionalized cyclodextrins enhance chiral recognition by a variety of means. In some cases, the groups mainly serve to extend the chiral cyclodextrin cavity and in others they may provide alternate interaction sites. For example, in the case of the naphthylethylcarbamoylated cyclodextrin the naphthyl ring provides a π-basic site while the carbamate linkage provides additional hydrogen bonding and dipolar interaction sites. The sulfate group on the sulfated cyclodextrin provides the potential for ion-pair formation while the two hydroxypropyl substituents add additional stereogenic centers to the cyclodextrin. One feature that is particularly advantageous with these functionalized cyclodextrins is that they often exhibit enantioselectivity in the hydroorganic reversed-phase as well as normal phase, and polar organic mobile phase conditions. This is unusual in that each mode can provide chiral separations for compounds, which are not resolved under any other types of mobile phase conditions.

Most chiral separations reported to date using the cyclodextrin columns have been accomplished in the reversed-phase mode using aqueous buffers with a small amount of organic modifiers. However, polar organic mobile phases have gained in popularity recently because of their ease of sample removal and reduced rate of column degradation.[1,71] In these cases, the solutes are thought to occupy the top of the cyclodextrin cavity like a ''lid'', rather than fit in the cavity because of the more nonpolar mobile phase. The commonly used mobile phases in the normal phase mode of separations are hexane–isopropanol. Separation in the normal phase mode is thought to be analogous to those of diol columns.

8.3 Separation Mechanism

The separation mechanism thought to be responsible for the chiral recognition observed with the cyclodextrin-bonded phases is based upon the formation of inclusion complex between the hydrophobic moiety of the solute and the hydrophobic cavity of the cyclodextrin.[63,69] This has been demonstrated by performing a separation in a normal phase mode using hexane–isopropanol mobile phase on a β-cyclodextrin column, a system by which the solute is excluded from the cyclodextrin cavity because a more hydrophobic mobile phase occupies the cavity. The inclusion complex formed between the solute and cyclodextrin cavity should also be a tight fit. This is apparent by the fact that better enantioresolution using a β-cyclodextrin column is obtained when the solute is about the size of biphenyl or naphthalene than when smaller or larger size solutes are used.[72] It is possible that smaller compounds may not be rigidly held in the cavity, resulting in a less stable diastereomeric complex and subsequently less successful separation. Moreover, the stereogenic center of the solute or the substituent attached to the stereogenic center of the solute should be able to interact with the rim of the cyclodextrin cavity in order to create strong interactions necessary for chiral separations.

The restricted conformational freedom of the 2- and 3-hydroxyl groups at the cyclodextrin rim is thought to play an important role for the chiral recognition properties in the cyclodextrins. This is evident by the modeling studies using (*R*)- and (*S*)-propanolol with β-cyclodextrin.[69] The (*R*)- and (*S*)-propanolol were placed inside the cyclodextrin cavity in an identical manner, and with the 3-hydroxyl group of the cyclodextrin lined up for an ideal hydrogen bonding with the hydroxyl groups on (*R*)- and (*S*)-propanolol as shown in Figure 4. An important difference which exists between the two complexes formed is at the secondary amine group. In the (*R*)-complex, the bond distances between the nitrogen on the amine group of the solute and the 2-

Figure 4 Computer projections of inclusion complexes of (a) *d*-propranolol and (b) *l*-propranolol in β-cyclodextrin from X-ray crystallographic data. (Reprinted by permission from the American Association for the Advancement of Science.[69])

and 3-hydroxyl groups on the cyclodextrin are 0.33 and 0.28 nm, respectively. In contrast, the (*S*)-complex has the respective bond distances of 0.38 and 0.45 nm. The model suggests that (*R*)-propanolol is positioned more favorably for hydrogen bonding with the cyclodextrin, and can preferentially interact with the chiral selector in a way that the (*S*)-isomer cannot. This difference in their interaction results in enantiorecognition.

9 THE MACROCYCLIC ANTIBIOTIC CHIRAL STATIONARY PHASES

The macrocyclic antibiotics and their derivatives have formed one of the newest and perhaps more versatile class of chiral selectors in HPLC.[73] They are excellent chiral selectors, and can be bonded to silica gel via linkage chains using a variety of chemistries. They can be used in either the reversed-phase or the normal phase mode. Enantioselectivities in each mode have been shown to be different. Furthermore, the macrocyclic antibiotics can be derivatized to alter their selectivity. The bonded macrocyclic antibiotic CSPs resemble the protein-based CSPs in many ways. However, the macrocyclic antibiotic CSPs are more stable and have greater capacities than the protein-based CSPs. There are literally hundreds of macrocyclic antibiotics that have yet to be investigated. Their versatility in enantioresolving chiral analytes is becoming well known. Thus far, the two most successful structural types of antibiotics used for separations are *ansa* compounds and glycopeptides. These two classes of macrocyclic antibiotics will be the focus of our discussion.

9.1 Properties and Structures

The ansamycins include *ansa* compounds such as rifamycin B, rifamycin SV, rifamide, and rifampim. They are isolated from the fermentation broth of the bacteria *Nocardia mediterranei*.[74] These compounds contain a characteristic *ansa* structure, a ring structure or chromophore that is spanned by an aliphatic chain. As shown in Figure 5, the rifamycins differ from each other only in the type and the location of the substituents on their naphthohydroquinone ring. Of the rifamycins, rifamycin B is one of the more common members and has been utilized as a CSP for HPLC. Rifamycin B has nine stereogenic centers, four hydroxyl groups, one carboxylic acid moiety, and one amide bond. Rifamycin B has a molecular weight of 756 and is more soluble in ethanol and methanol

Figure 5 (a) Structure of rifamycin B (R = $-CH_2COOH$) and SV (R = $-OH$). Simplified schematic showing (b) rifamycin SV and (c) rifamycin B.

Table 3 Comparison of the physico-chemical properties of the macrocyclic antibiotics

Characteristic	Rifamycin B	Vancomycin	Thiostrepton	Teicoplanin
Molecular weight	755	1449	1665	1877
Stereogenic centers	9	18	17	23
No. of OH groups	4	9	5	15
No. of amine groups	0	2	1	1
No. of carboxylic acids	1	1	0	1
No. of amido groups	0	7	10	7
No. of aromatic groups	2	5	7	7
No. of methyl esters	1	0	0	0
pI	–	7.2	–	4.2

than in water. The substituent on rifamycin B is an oxyacetic acid ($-OCH_2COOH$), thus the carboxylic and the hydroxyl groups on rifamycin B are ionizable and rifamycin B can exist as a dibasic acid.

The glycopeptide macrocyclic antibiotics vancomycin, thiostrepton, and teicoplanin are produced by *Streptomyces orientalis*, *Streptomyces azureus*, and *Actinoplanes teichomyceticus*, respectively.[75,76] The glycopeptide macrocyclic antibiotics are soluble in water, buffers, and acidic aqueous solutions, and are less soluble at neutral pH. They are moderately soluble in polar aprotic solvents, such as dimethyl sulfoxide (DMSO) and dimethyl formamide (DMF), but are insoluble in most nonpolar organic solvents. The three glycopeptide macrocyclic antibiotics have many structural features and physico-chemical properties in common. Table 3 shows a comparison of the macrocyclic antibiotics.

Among the three glycopeptide macrocyclic antibiotics discussed, vancomycin **(26)** is the smallest in size (molecular weight 1449, 18 stereogenic centers) while thiostrepton **(27)** is of intermediate size (molecular weight 1665, 17 stereogenic centers), and teicoplanin **(28)** is the largest in size (molecular weight 1877, 23 stereogenic centers).[73,77,78] The macrocycles contain both ether and peptide linkages. The aglycon portion of vancomycin and teicoplanin consists of two chloro-substituted aromatic rings. In thiostrepton the analogous portion lacks a chloro-substituent. There is a carboxylic moiety on the aglycon of both vancomycin and teicoplanin. Thiostrepton contains in its aglycon portion five thiazole rings and one quinoline ring. The type and number of pendant carbohydrate moieties vary among the glycopeptide macrocyclic antibiotics as well. Vancomycin contains D-glucose and vancosamine. Teicoplanin, on the other hand, has three attached monosaccharides, two D-glucosamines and one D-mannose. Thiostrepton has no attached carbohydrate moieties.

In addition to the fused macrocyclic rings and the attached pendant carbohydrate moieties, the glycopeptide macrocyclic antibiotics have various analogous ionizable groups, which are thought to control their charge and enantioselective properties. For example, vancomycin and thiostrepton have a secondary amine unlike teicoplanin, which contains only a primary amine group.

(28)

9.2 Applications

Currently, there are two types of glycopeptide-based CSPs available commercially: vancomycin and teicoplainin. The macrocyclic antibiotics can be attached to silica gel via epoxy-terminated organosilane, as has been used with the cyclodextrins, or by reacting the macrocyclic antibiotics with an isocyanate-terminated organosilane in anhydrous DMF. The macrocyclic antibiotics are multimodal CSPs. These CSPs can be useful in preparative-scale separations. They can be used effectively in the reversed-phase, normal phase, and polar organic modes. Different compounds are resolved in each mode.[77] When changing from one mode to another, there does not appear to be any deleterious effects to the stationary phases or any irreversible changes in the enantioselectivity. The macrocyclic antibiotics have been shown to exhibit excellent enantioselectivity for native amino acids, peptides, α-hydroxycarboxylic acids, and a variety of neutral analytes including cyclic amides and amines. Neutral molecules, for example, devrinol and 5-methyl-5-phenylhydantoin, seem to show considerable enantioselective retention on the macrocyclic antibiotic CSPs. The chiral selectors appear to be stable and the integrity of the CSP is excellent in all separation modes. For example, compounds resolved in reversed-phase mode using vancomycin-bonded phase column include bromacil, devrinol and coumachlor enantiomers whereas in normal mode the same column showed enantioselectivity for 3-[2-(2-bromoacetamido)acetamido]-PROXYL and *N*-(3,5-DNB)-α-methylbenzalamine.[77] Of the available modes, the reversed-phase mode is probably more widely employed when using the macrocyclic antibiotics as a CSP.

In comparison to the other two CSPs most often used in the reversed-phase mode, which are the protein columns and the cyclodextrin-based columns, the macrocyclic antibiotic stationary phases have similarities and differences with both of these classes. Similar to the protein columns, the macrocyclic antibiotics contain ionizable groups, and consequently their charge and possibly conformation can vary with the pH of the mobile phase. The effect of mobile phase pH, however, is not observed when using the cyclodextrin CSPs because the cyclodextrins remain neutral at pH 3–8.5, which is the pH range commonly used in reversed-phase HPLC. Like the protein phases and the cyclodextrin phases, it is not necessary to derivatize racemic analytes before separation on the macrocyclic antibiotic CSPs. Most macrocyclic antibiotics contain peptide bonds, some have carbohydrate moieties, and a few, such as vancomycin, have both features.

Optimization of reversed-phase separations can be achieved in a similar way as for cyclodextrin-based columns. Retention can be changed by varying the amount of organic modifier, such as acetonitrile and methanol, and the mobile phase pH. For example, using teicoplanin CSP, with 100% triethylammonium acetate pH 7 buffer, 5-methyl-5-phenylhydantoin has a $k > 4$, where k is the capacity factor, but with acetonitrile–1% triethylammonium acetate pH 7 buffer (60 : 40 v/v), k is nearly zero or the analyte elutes near the dead volume of the column.[78] A plot of retention vs mobile-phase composition shows the same U-shaped curve, which has been observed previously for chiral solutes on cyclodextrin-based columns and for proteins and peptides on reversed-phase columns. Typical normal phase retention behavior is found on a teicoplanin column. Retention and enantioselectivity are highest when the mobile phase consists mainly of the nonpolar component, such as hexane. Both retention and selectivity decrease as the amount of ethanol in the mobile phase is increased.

In addition, efficiency and selectivity can be affected by ionic strength, type of buffer, flow rate, and other additives. On a teicoplanin column under a normal phase mode, flow rate does not affect enantioselectivity or α, but does affect the separation efficiency. This is reflected by the inverse relationship between resolution (R_S) and flow rate. Decreasing the flow rate increases the resolution. However, decreasing the flow rate below 0.5 mL min^{-1} does not continue to produce an increase in resolution. It is believed that this is the result of poor stationary phase mass transfer. Temperature also has been shown to affect chiral separations using the macrocyclic antibiotic CSPs. Lowering the temperature appears to enhance enantioseparations by increasing α. Using the reversed-phase mode on a vancomycin CSP, the separation of *N*-carbamyl-D,L-phenylalanine increased α of 1.00 and R_S of 0 to α of 1.23 and R_S of 1.0 upon decreasing the temperature from 45 °C to 15 °C.[77] Lowering the temperature in general enhances resolution and selectivity but concurrently causes an increase in retention time.

9.3 Separation Mechanism

It is thought that the size, shape, geometric arrangement, as well as the functional groups present in the macrocyclic antibiotics, help to determine their enantioselective properties. In addition to the charge interactions, the retention behavior of organic analytes in the reversed-phase mode indicates the importance of hydrophobic interactions between the analyte and the macrocyclic antibiotics. However, whether or not there is a true inclusion complex between the chiral selector and the analyte as in the case of the cyclodextrins or just an association of the analyte with the hydrophobic pocket is not known. Hydrogen bonding is believed to be essential for enantiorecognition, particularly in acetonitrile mobile phases.

10 FUTURE TRENDS

The development and success of the various CSPs have had a profound impact not only on the field of analytical separations but also the pharmaceutical industries, and other industries that manufactured or marketed chiral compounds. CSPs have been beneficial to the understanding of molecular recognition, chromatographic theory, and mechanism. In the future, chiral separations have the potential to aid in our understanding of the chemistry behind biological processes, diseases, and probing intermolecular interactions. Mechanistic studies of chiral compounds as well as CSPs will undoubtedly continue in the future.

1 INTRODUCTION

Chromatography is a general term applied to a wide variety of separation techniques based upon the sample partitioning between a moving phase, which can be a gas, liquid, or supercritical fluid and a stationary phase, which may be either a liquid or a solid. The discovery of chromatography is generally credited to Tswett[1] who in 1906 described his work on using a chalk column to separate pigments in green leaves. The term ''chromatography'' was coined by Tswett to describe the colored zones that moved down the column. The technique languished for years with only periodic spurts of development following innovations such as partition and paper chromatography in the 1940s, gas chromatography (GC) and thin-layer chromatography in the 1950s, and various gel or size-exclusion methods in the early 1960s.[2] Then in January, 1969, the *Journal of Gas Chromatography* officially changed its name and became the *Journal of Chromatographic Science*. This change reflected the renewed interest in the technique of liquid chromatography (LC) and officially signaled the beginning of the era of modern LC. This renewed interest in the oldest of chromatographic techniques was brought about both because of the successes and because of the failures of GC. On the one hand, GC provided a firm theoretical background upon which modern LC could build. However, this renewed interest in LC was being driven because of the inability of GC to handle thermally unstable or nonvolatile compounds. It has been estimated that fewer than 20% of organic compounds have sufficient volatility and thermal stability to successfully traverse a GC column. Admirers of LC also liked the selective interaction of its two chromatographic phases, and easy sample recovery because of its nondestructive detection methods and room temperature operation.

In the following years the technique was known by many acronyms. It was at various times designated high-pressure liquid chromatography, high-speed liquid chromatography, high-performance liquid chromatography (HPLC), high-priced liquid chromatography by cynical research directors, and finally modern liquid chromatography. The modifiers were all used to signify the difference in the technique brought about by small particle diameter stationary phases and the resulting high pressure needed to drive the mobile phase through the densely packed columns. These differences resulted in much faster separations with higher resolution than traditional column chromatography. Through the 1970s the technique grew with astounding speed, and for nine consecutive years from the middle of the 1970s to the early 1980s the technique led all other analytical instruments in growth rate in an annual survey conducted by the *Industrial Research and Development* magazine.

A discussion of the history of LC is beyond the scope of this volume; an excellent treatment has been published by Ettre.[3] However, some perspective on the beginnings of modern LC is useful for an understanding of the technique as now practiced. The first comprehensive publication on the technique was a book edited by Kirkland,[4] which grew from a short course offered by the Chromatography Forum of the Delaware Valley. This then laid the foundation for the definitive book, now in its second edition, *Introduction to Modern Liquid Chromatography*.[2]

During the development of modern LC, advances have been driven by both instrumentation and chemistry. The technique as now practiced produces elegant separations that have been developed through chemical manipulation of the stationary and mobile phases, which are then effected and detected by modern instrumentation.

2 FUNDAMENTALS OF CHROMATOGRAPHY

Chromatography is a separation method which employs two phases, one stationary and one mobile. As a mixture of analytes being carried through the system by the

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

mobile phase (m) passes over and through the stationary phase (s), the individual components (X) of the mixture equilibrate or distribute between the two phases:

$$X_m \longleftrightarrow X_s$$

The corresponding thermodynamic distribution coefficient K is defined as the concentration of component (X) in the stationary phase divided by its concentration in the mobile phase, as shown in Equation (1).

$$K = \frac{[X]_s}{[X]_m} \tag{1}$$

The use of a typical equilibrium constant K in chromatographic theory indicates that the system can be assumed to operate at equilibrium. As the analyte (X) proceeds through the system, it partitions between the two phases and is retained in proportion to its affinity for the stationary phase. At any given time, a particular analyte molecule is either in the mobile phase, moving at its velocity, or in the stationary phase and not moving at all. The individual properties of each analyte control its thermodynamic distribution and retention, and result in differential migration of the components in the mixture; the basis of the chromatographic separation. The effectiveness of the separation, however, is a function of *both* thermodynamics and kinetics.

2.1 Thermodynamic Considerations

In order to understand the thermodynamic considerations of the separation process, we need to look at the basic equations which describe the retention of a solute and relate the parameters of retention time, retention volume, and retention factor to the thermodynamic solute distribution coefficient.

Figure 1 shows a model chromatogram for the separation of two compounds. The time required for the elution of a retained compound is given by t_r, the retention time, and is equal to the time the solute spends in the moving mobile phase plus the time spent in the stationary phase, not moving. If a solute is unretained and has no interaction with the stationary phase, it will elute at t_0, the hold-up time or dead time, which is the same time required for the mobile phase solvent molecules to traverse the column.

Figure 1 A model chromatogram for the separation of two compounds, **1** and **2**, by column chromatography.

Another fundamental measure of retention is retention volume, V_r. It is sometimes preferable to record values of V_r rather than t_r since t_r varies with the flow rate F, while V_r is independent of F. If we wish to describe the volume of the mobile phase required to elute a retained compound, then the retention volume is the product of the retention time and the mobile phase flow rate, as shown in Equation (2).

$$V_r = t_r F \tag{2}$$

V_0 is a measure of the total volume of space available to the mobile phase in the system and correlates to t_0 as the *volume* necessary to elute an unretained compound. This is shown in Equation (3):

$$V_0 = t_0 F \tag{3}$$

The most commonly used retention parameter in HPLC is the retention factor, k'. While the distribution coefficient, K, describes the concentration ratios, the retention factor, k', as shown in Equation (4), is the ratio of the amount of solute in each phase.

$$k' = \frac{\text{moles of X in stationary phase}}{\text{moles of X in mobile phase}} = \frac{[X]_s V_s}{[X]_m V_m} = \frac{K V_s}{V_m} \tag{4}$$

Equation (4) shows that k' is directly proportional to V_s, and so k' for each solute changes with the stationary phase loading on the silica support.

The retention factor is conveniently measured from retention parameters, as shown in Equation (5), since k' also describes the amount of time the solute spends in each phase.

$$k' = \frac{t_r - t_0}{t_0} = \frac{V_r - V_0}{V_0} \tag{5}$$

Rearrangement of Equation (5) gives Equation (6):

$$V_r = V_0(1 + k') \tag{6}$$

The retention volume can then be related to the distribution coefficient by substituting Equation (4) for k' in Equation (6), where $V_m = V_0$. This gives Equation (7):

$$V_r = V_0 + K V_s \tag{7}$$

2.2 Kinetic Considerations

It is obvious from Figure 1 that the chromatographic separation of components in a mixture is dependent on

two factors; the difference in retention times of two adjacent peaks, or more precisely the difference between peak maxima, and the peak widths. It was shown in the preceding discussion that the retention of a solute is a thermodynamic process controlled by the distribution coefficient and the stationary phase volume. The peak width, or band broadening, on the other hand is a function of the kinetics of the system.

Early papers on chromatographic theory described the technique in terms similar to distillation or extraction. The Nobel Prize winning work by Martin and Synge[5] in 1941 introduced liquid–liquid (or partition) chromatography and the accompanying theory that became known as the *plate theory*. Although the plate theory was useful in the development of chromatography, it contained several poor assumptions. The theory assumed that equilibration between phases was instantaneous, and that longitudinal diffusion did not occur. Furthermore, it did not consider dimensions of phases or flow rates. An alternative to the plate theory which came into prominence in the 1950s was the so-called "*rate theory*". The paper which has had the greatest impact was the one published by van Deemter et al.[6] They described the chromatographic process in terms of kinetics and examined diffusion and mass transfer. The popular van Deemter plot resulted and the rate theory has become the backbone of chromatographic theory.

Several processes, which will be discussed shortly, contribute to the overall width of the band, and the contribution from each process can be described in terms of the variance (σ^2) of the chromatographic peak, which is the square of its standard deviation (σ).

The most common measure of efficiency of a chromatographic system is the plate number, N. Because the concept originated from the analogy with distillation, it was originally called the number of theoretical plates contained in a chromatographic column. This is not a useful analogy since a chromatographic column does not contain "plates" but the terminology has become universally adopted and the original definition has persisted. The expression for the efficiency of a column is given by Equation (8).

$$N \equiv \left(\frac{t_r}{\sigma_t}\right)^2 \tag{8}$$

where σ_t is the standard deviation in time units; the parameters t_r and σ_t must be measured in the same units so the number N is dimensionless.

For Gaussian peaks we can express σ in terms of peak width where the width of the peak at the baseline (w_b) is equal to 4σ (see Figure 2). N is then given by Equation (9):

$$N = \left(\frac{t_r}{\sigma_t}\right)^2 = 16\left(\frac{t_r}{w_b}\right)^2 \tag{9}$$

Figure 2 Evaluation of a chromatographic peak for the calculation of column efficiency.

Because measurements depending on w_b rely on the accurate positioning of tangents to the chromatographic peak, another common calculation of N uses the more easily measured peak width at half height, $w_{0.5}$, where $w_{0.5} = 2.354\sigma$, as shown in Equation (10):

$$N = \left(\frac{t_r}{\sigma_t}\right)^2 = 5.54\left(\frac{t_r}{w_{0.5}}\right)^2 \tag{10}$$

The assumption for the measurement of peak widths in Equations (8–10) is that the peak is Gaussian. Unfortunately, few peaks are truly Gaussian and in general, for asymmetrical peaks, N, calculated by a Gaussian-based equation, increases the higher up on the peak the width is measured. Figure 3 shows the

Figure 3 Plot of percentage error in plate count determinations for asymmetrical peaks as a function of peak height at which the width is measured. The quantities B and A are illustrated in Figure 4. (Adapted from Foley and Dorsey.[7])

Figure 4 Plot of normalized peak height vs. time.

error in plate count determinations for asymmetrical peaks as a function of the peak height at which the width is measured. A more accurate approach to efficiency measurement, shown in Equation (11), has been presented by Foley and Dorsey[7] which takes into account the peak asymmetry.

$$N = \frac{41.7(t_r/w_{0.1})^2}{1.25 + (B/A)} \tag{11}$$

Here the peak width is measured at 10% of peak height and the asymmetric ratio or tailing factor is calculated as the ratio of B/A (see Figure 4). For a symmetrical peak, the B/A value will be 1, and the tailed peaks will have values greater than 1.

The plate number depends on the column length, making comparisons among columns difficult unless they are all of the same length. Another measure of efficiency which removes this dependency is given by the plate height, as shown in Equation (12):

$$H = \frac{L}{N} \tag{12}$$

where L is the length of the column. H can thus be thought of as the length of the column that contains one plate. For the highest efficiencies, the goal is to attain maximum N and small H values. We will see that H is proportional to the diameter of the stationary phase particles, so a better measure of expressing efficiency is the reduced plate height, h, given by Equation (13):

$$h = \frac{H}{d_p} \tag{13}$$

where d_p is the stationary phase particle diameter. The reduced plate height is a dimensionless number (H and d_p being measured in the same units) and this calculation allows us to compare efficiencies of columns with different particle diameters. A well operated chromatographic system should have h values of 2 to 5.

As mentioned earlier, the extent of band broadening, and thus the efficiency of a chromatographic column, is dependent on several contributing processes. The four important band broadening phenomena to be considered are: (i) resistance to mass transfer (rmt); (ii) eddy diffusion (ed); (iii) longitudinal diffusion (long); and (iv) extra-column effects (ex). Each of these independently would produce a Gaussian band. The variances of each band broadening process are additive to give the overall variance of the system, as shown in Equation (14):

$$\sigma_t^2 = \sigma_{rmt}^2 + \sigma_{ed}^2 + \sigma_{long}^2 + \sigma_{ex}^2 \tag{14}$$

2.2.1 Resistance to Mass Transfer

As solute molecules interact with the column packing they continually transfer into and out of the stationary phase. Resistance to mass transfer relates to the rate at which the molecules exchange between phases and may be the dominant cause of band spreading.

If there were no flow through the column, there would be an equilibrium distribution of the analyte molecules between the mobile and stationary phases according to its partition coefficient. However, since there is flow, molecules in the mobile phase are swept downstream creating a condition of nonequilibrium in the immediately adjacent stationary phase. In order to restore the system to equilibrium, some molecules left behind in the stationary phase must desorb and enter the mobile phase, and some that were carried ahead must leave the mobile phase and sorb onto the stationary phase. This mass transfer takes a finite time and results in band broadening. The faster the mass transfer occurs, the less will be the effect. Both the stationary and mobile phase play a role in determining the rate of mass transfer. A discussion of all the contributing factors is given by Giddings,[8] but three of the most important are the diffusion coefficient of the solute in the mobile phase (D_m), the stationary phase particle diameter (d_p), and mobile phase flow velocity (v). The relationship is shown by Equation (15):

$$\text{rate of mass transfer} \propto \frac{d_p^2 v}{D_m} \tag{15}$$

A molecule is in constant motion in solution. The larger the volume of mobile phase the molecule is in, the longer it will take to diffuse to a phase boundary. In chromatographic columns, the interstitial volume between particles is of the order of the same size as the particles themselves. Small particle diameter packings

therefore result in a much higher rate of contact and a greater rate of mass transfer. A high rate of diffusion of the solute in the mobile phase also increases the rate of contact by decreasing the time for the molecule to move between stationary phase particles. For this reason, many chromatographers choose low viscosity solvents as eluents and/or operate the system at elevated temperatures to increase the diffusion coefficient of the solute in the mobile phase.

The contribution to band broadening by flow velocity is obvious, since the faster the mobile phase is flowing, the farther molecules will be swept downstream before they exchange phases.

2.2.2 Eddy Diffusion

The velocity of the liquid moving through a column may vary significantly across the diameter of the column depending on the bed structure. The velocity of solutes being carried through the column by the mobile phase will therefore fluctuate between wide limits, and the total distance traveled by individual molecules will also vary. These variations are a result of different flow paths taken as a function of least resistance. Since the average velocity of the solute determines its retention time, these random fluctuations result in band broadening. There is still much disagreement about quantitation of this effect, but a generally accepted proportionality is given by Equation (16):

$$\text{eddy diffusion} \propto d_p V^{1/3} \tag{16}$$

The smaller the stationary phase particle diameter the closer will be the packing. This minimizes the variation in flow paths available to the molecules and reduces band broadening. High flow velocities affect the band broadening by causing molecules traveling though open pathways to move more rapidly than those in narrow pathways. The simple theory of eddy diffusion assumes that a particle will remain in a single flowpath. In practice, this is not the case since there is nothing to stop it from diffusing laterally from one flow path to another. This process, called ''coupling'', averages out the two flowpaths and reduces the band broadening so that the final band width, although still greater than the initial band width, is less than if coupling had not occurred. So, rather than a direct relationship to flow velocity, as theory would predict, eddy diffusion is more nearly proportional to velocity to the 1/3 power.

2.2.3 Longitudinal Diffusion

As solute bands move through a column, diffusion of molecules into the surrounding solvent occurs from the region of higher concentration to the region of lower concentration in proportion to the diffusion coefficient, D_m, according to Fick's law. The faster the mobile phase moves, the less time the zone is in the column, the less time there is for diffusion, and the lower the band broadening due to diffusion. The relationship for longitudinal diffusion, D_{long}, is given by Equation (17):

$$D_{long} \propto \frac{D_m}{V} \tag{17}$$

In principle, longitudinal diffusion may occur in both mobile and stationary phases, but because the rate is so small in the stationary phase, this factor can be neglected.

Combination of the three terms (resistance to mass transfer, eddy diffusion and longitudinal diffusion) gives the well known van Deemter expression shown in Equation (18):

$$H = A + \frac{B}{v} + Cv \tag{18}$$

where the A term is due to eddy diffusion, the B term is due to longitudinal diffusion, and the C term is due to resistance to mass transfer. The familiar van Deemter plot is shown in Figure 5. This equation is also often written with reduced plate height and velocities, and is then known as the Knox equation.

2.2.4 Extra-column Effects

Band broadening can occur in other parts of the chromatographic system as well as in the column. Contributions to this extra-column broadening may come from the injector, the detector flow cell, and the connecting tubing. Slow time constants of detectors and recorders may also contribute. These extra-column effects are more severe for early, narrow peaks in the chromatogram than for later, broader peaks.

Figure 5 Van Deemter plot applied to LC.

2.3 Resolution

We have seen that the effective separation of two peaks is a function of both thermodynamic and kinetic effects. A common measure of the separation, the resolution, is the ratio of the distance between peak maxima and the average peak width.

$$R_s = \frac{\text{peak separation}}{\text{average peak width}} \quad \begin{matrix}\text{(thermodynamic)} \\ \text{(kinetic)}\end{matrix} \tag{19}$$

In order to obtain peak separation, one of the components in a mixture must be more selectively retained than another, or we may say the column showed selectivity toward the components in the mixture. Selectivity is measured by the separation factor or relative retention (α) and may be given by any of relationships shown in Equation (20):

$$\alpha_{2,1} = \frac{K_2}{K_1} = \frac{k'_2}{k'_1} = \frac{t'_{r2}}{t'_{r1}} = \frac{t_{r2} - t_m}{t_{r1} - t_m} \tag{20}$$

The relationship between the separation factor and the distribution coefficients K_2 and K_1 of the two components (2) and (1) emphasizes the thermodynamic basis of the separation.

Figure 6 illustrates the influence on resolution of peak separation and peak width. Figure 6(a) shows two components poorly resolved because of inadequate selectivity and large band widths. Figure 6(b) shows the components with the same band widths but good resolution as a result of improved selectivity. Figure 6(c) also demonstrates good resolution, but here narrow band widths are the contributing factor even though the selectivity is unchanged. The quantitative measure of resolution is given by Equation (21).

$$R_s = \frac{2(t_{r2} - t_{r1})}{w_1 + w_2} \tag{21}$$

In practice, it is seldom necessary to calculate the value of resolution. More frequently, the chromatographer simply looks at the shape of the peaks and estimates the R_s value from the peak shape. Of course, the concentrations and/or responses of the components in a mixture are rarely equal. Figure 7 illustrates the significance of the resolution value for two components with different relative concentrations.

The chromatographic control of resolution is a function of several factors. The fundamental resolution equation is shown in Equation (22):

$$R_s = \left(\frac{N^{1/2}}{4}\right)\left(\frac{\alpha - 1}{\alpha}\right)\left(\frac{k'}{k' + 1}\right) \tag{22}$$

where $\alpha = k'_2/k'_1$.

The plate number N (column factor) can be increased by lengthening the column, changing the packing particle diameter, or optimizing flow rate. However, improving resolution by increasing N is expensive in time. Doubling the column length doubles the elution time, solvent consumption, and pressure while only increasing R_s by 1.4. Likewise, reducing the particle diameter increases the resolution but may exceed the maximum allowable pressure.

Figure 6 Two-component chromatograms to illustrate the importance of peak-to-peak separation and peak widths on separation.

Figure 7 Significance of resolution values for two components with different relative concentrations.

The selectivity α (thermodynamic factor) can be increased by changing columns to a different stationary phase or by imposing secondary equilibria through changes in mobile phase pH or the addition of complexing agents to the mobile phase, for example. In order to discuss the effect of selectivity changes, it is necessary to rearrange Equation (22) and solve for N, as shown in Equation (23):

$$N_{\text{req}} = 16R_s^2 \left(\frac{\alpha}{\alpha - 1}\right)^2 \left(\frac{k' + 1}{k'}\right)^2 \qquad (23)$$

If we assume $R_s = 1.0$ and $k' = 2$, then

$$\alpha = 1.01 \qquad N_{\text{req}} = 367\,000$$
$$\alpha = 1.05 \qquad N_{\text{req}} = 16\,000$$

Changing α to 1.05 gives us a 96% reduction in required column efficiency which translates to a 96% reduction in column length, analysis time, solvent consumption, and solvent disposal. Changing selectivity is certainly the most efficient way to improve resolution. However, the cost of changing α is in method development time.

Increasing the retention factor, k', can also increase resolution, particularly for early eluting compounds. This is done primarily by going to a weaker mobile phase. Looking at Equation (23) again, for $R_s = 1.0$, and $\alpha = 1.05$,

$$k_2' = 0.1 \qquad N_{\text{req}} = 854\,000$$
$$k_2' = 1.0 \qquad N_{\text{req}} = 28\,000$$
$$k_2' = 10.0 \qquad N_{\text{req}} = 8500$$

While a 97% decrease in required column efficiency is calculated for changing k' from 0.1 to 1.0, another 70% decrease occurs for a k' change from 1.0 to 10.0. It is clear from Equation (22) that as k' becomes large, the resolution is unaffected by small changes in k'. Changing k' to improve resolution thus has an upper limit of effectiveness at approximately $k' = 10$. This is illustrated in Figure 8.

2.4 Time Considerations

While any of the above methods will improve resolution, they are far from equal in terms of their effects on time. Recalling that $t_r = t_0(1 + k')$, and $H = L/N$, and realizing $t_0 = L/v$, where v is the average flow velocity, then $t_0 = HN/v$. So, $t_r = (HN/v)(1 + k')$ and rearranging gives Equation (24):

$$N = \frac{t_r v}{H} \frac{1}{1 + k'} \qquad (24)$$

Figure 8 Resolution of a pair of peaks as a function of k'. Plate count N is 10 000 and α is 1.04.

Setting Equation (24) equal to Equation (23) and solving for t_r gives Equation (25):

$$t_r = 16R_s^2 \left(\frac{\alpha}{\alpha - 1}\right)^2 \frac{(k' + 1)^3}{k'^2} \frac{H}{v} \qquad (25)$$

We can see that to double the resolution by increasing N (holding α, k', H and v constant) requires a four-fold increase in time.

In the previous section we saw how changes in selectivity can improve resolution while decreasing analysis time. If we assume $N = 10\,000$ and $k' = 2$, and further if we could manipulate chromatographic conditions such that k_2' would remain unchanged as we change selectivity, then by Equation (22) a change in α from 1.01 to 1.05 would increase resolution from 0.2

Figure 9 Plot of $(k' + 1)^3/(k')^2$ vs k'.

to 0.8. We can see from Equation (25) then that with this improvement in resolution and the stated change in selectivity (holding H and v constant), that retention time would decrease by a factor of $t_{r2}/t_{r1} = 0.9$, or 10%.

Figure 9 shows that the $(k' + 1)^3/(k')^2$ term in Equation (25) goes to infinity at both large and small values of k'. Thus, in the effective range of k' values from 1 to 10 (holding H and v constant, and assuming $\alpha = 1.05$ and $N = 10\,000$) the resolution would improve by a factor of 1.8 with a reduction in analysis time of 66%.

We know we can reduce analysis time by shortening the column, but we have a required efficiency necessary to separate the components in a mixture with the desired resolution. Assuming a well operating chromatograph yielding a reduced plate height of three, 10 000 plates can be generated with 10 µm diameter particles in 30 cm, with 5 µm particles in 15 cm, or with 3 µm particles in 9 cm. Assuming a solute with a retention factor of 2, the retention volume for these columns would be 9.0, 4.5 and 2.7 mL, respectively, and the peak base width would be 360, 180 and 108 µL, respectively.

2.5 Peak Capacity

Peak capacity (PC), defined in Equation (26), is the maximum number of components in a mixture that can be resolved with a resolution of one between the inert peak and the last peak.

$$\mathrm{PC} = 1 + \left(\frac{N^{1/2}}{4}\right) \ln(1 + k') \qquad (26)$$

As samples become more complex, the ability of a particular separation method to resolve all components decreases. A statistical study of component overlap has shown that a chromatogram must be approximately 95% vacant to provide a 90% probability that a given component of interest will appear as an isolated peak.[9] This is shown graphically in Figure 10 where the probability of separation is plotted as a function of the system peak capacity for cases where the number of components varies from 10 to 70. A thorough discussion of resolving power is given by Martin et al.[10]

Figure 10 Plots of the probability that all (m) sample components will be separated, Pb($p = m$), as a function of the system peak capacity, n, for the representative cases where $m = 10, 30, 50$ and 70. (Adapted from Martin et al.[10])

Elution chromatography can be carried out in either isocratic or gradient modes. In isocratic elution, the mobile-phase composition is held constant during separation of the sample, e.g. 60% v acetonitrile–water. In gradient elution, the mobile-phase composition will be varied during sample separation, e.g. changing from 0 to 100% v acetonitrile–water. Gradient elution requires special chromatographic equipment, as well as somewhat greater care on the part of the operator, but it has important advantages for many separations. Thus, in isocratic elution (Figure 1a), sample peaks tend to "bunch up" at the beginning of the chromatogram (often with decreased resolution) and to broaden at the end of the chromatogram (with reduced detection sensitivity). Gradient elution (Figure 1b), on the other hand, provides a more even spacing of peaks, similar widths throughout the chromatogram, and often a shorter run time. For these and other reasons, gradient elution is preferred for the separation of many samples.

1 INTRODUCTION

1.1 Characteristic Features

Gradient elution represents an alternative to isocratic separation and it is therefore useful to begin with a comparison of the two techniques. In isocratic elution, sample retention can be controlled by varying the composition of a mobile phase composed of a "weak" solvent A and a "strong" solvent B. An example is shown in Figure 2, for the separation of the *o*-dialkylphthalate sample of Figure 1 with a reversed-phase C_{18} column and mobile phases composed of water (A) and acetonitrile (B). An increase in % B from 50% B in Figure 2(a) to 70% B in Figure 2(b) results in decreased sample retention and a shorter run time. In isocratic separation as in Figure 2, the separation of any two adjacent peaks is critically dependent on % B. As the concentration of B increases and sample retention decreases, this in turn results in (1) reduced resolution, R_s, of the two bands, (2) decreased bandwidth and better detection sensitivity (taller peaks), and (3) a shorter run time as measured by the retention time, t_R, of the later-eluting band. For 50% B as mobile phase (Figure 2a), the separation of early bands C_2–C_4 is acceptable ($R_s > 1.5$), but later bands C_8–C_{10} require a long time for their elution from the column and are wider and therefore less easily detected. For 70% B as mobile phase (Figure 2b), later bands C_8–C_{10} leave the column in a much shorter time and are narrower and better detected; however, the separation of early bands C_2 and C_3 is poor ($R_s = 0.6$).

The isocratic separation of the *o*-dialkyl phthalate sample of Figures 1(a) and 2 is never completely satisfactory, regardless of the choice of mobile phase % B. The reason is that early bands require a weaker solvent (50% B in Figure 2a), while later bands benefit from a stronger solvent (70% B). The advantage of gradient elution for samples such as this is that each component of the sample can be eluted under conditions of optimum retention. Thus, in gradient elution all sample components are retained initially at the column inlet, because the starting mobile phase is usually quite weak and all bands initially have large values of k, the isocratic retention factor. As

Figure 1 Separation of a mixture of *o*-dialkyl phthalates by reversed-phase high-performance liquid chromatography (HPLC). Sample: alkyl homologs from dimethyl (C_2) to dipentyl (C_{10}). Conditions: 25 × 0.46-cm C_{18} column, acetonitrile (B)–water (A) mobile phases, 35 °C, 2 mL min^{-1}. (a) Isocratic separation with 60% B, (b) gradient separation: 0–100% B in 12 min. Computer simulations[1] based on data of Snyder et al.[2] with $N = 2000$.

Figure 2 Isocratic separation of *o*-dialkyl phthalate bands C_2 and C_3 as a function of % B. (a) 50% B, (b) 70% B. Other conditions as in Figure 1.

the mobile phase becomes progressively stronger during the separation (% B increases), early bands begin to move through the column and are separated under near-optimal conditions (lower % B). Later bands move through the column at a later time under conditions (higher % B) that are also better for separation. As a result, seen in the example of Figure 1(b), it is possible by means of gradient elution to achieve good resolution for both early and late eluting bands, similar bandwidths and comparable ease of detection, and a shorter separation time.

The mobile phase gradient can be described in terms of the dependence of % B on time during the separation, as illustrated in Figure 3 for several gradient shapes. In most cases, the use of linear gradients as in Figure 3(a) is preferable; linear gradients will be assumed in the following discussion unless noted otherwise. The gradient elution separation can be regarded as a series of small isocratic steps as in Figure 3(e). As a result, the basic principles of isocratic and gradient elution are similar, and it will prove useful to describe gradient separations in terms of ''corresponding'' isocratic separations, where the sample and all experimental conditions are the same except for the change in % B with time in gradient elution. For a more detailed discussion of gradient elution, see Jandera and Churacek,[3] Snyder et al.[4–6]

1.2 Advantages of Gradient Elution

Isocratic elution is a simpler procedure than gradient elution, and for this reason it is usually the preferred technique. However, there are several situations where gradient elution can be a better choice, as discussed below.

1.2.1 Samples with Widely Different Retention

If the sample of Figure 2(b) were limited to the later-eluting five components (C_6–C_{10}), the resulting separation with 70% B as mobile phase would be quite satisfactory, i.e. good resolution of all bands, good detectability for all bands, and a reasonable run time (14 min). The problem with the separation of the total sample (C_2–C_{10}) is that early bands (C_2–C_4) are weakly retained and later bands (C_8–C_{10}) are strongly retained. In isocratic elution it is desirable that all sample bands be eluted with a retention factor k that falls within a narrow range of values: e.g. $1 < k < 10$. When this is not possible, as in the example of Figures 1 and 2, no isocratic mobile phase can provide a ''good'' separation of the sample. This is the most common reason for using gradient elution and it is sometimes referred to as the general elution problem. We will refer to samples such as that in Figures 1 and 2 as having a retention range that is too wide for isocratic elution.

Figure 3 Different gradient shapes. (a) Linear, (b) convex, (c) concave, (d) segmented, (e) step gradient, (f) gradient delay and rounding. See text for additional details.

1.2.2 "Dirty" Samples

Many samples contain minor amounts of strongly retained components that are not of interest to the analyst. Examples include extracts of plant or animal tissue, environmental samples, and synthetic organic reaction mixtures. The repeated isocratic separation of such samples can result in a gradual accumulation of these "late eluters" on the column, with corresponding changes in sample retention, loss of column efficiency, and degradation of the baseline. For this reason, a frequent cleansing of the column may be required, as by washing the column with a strong solvent (e.g. 100% B). When gradient elution is used for the analysis of such samples, the column will be cleaned automatically by the strong mobile phase at the end of the gradient.

1.2.3 "Scouting" Runs During Method Development

The use of an initial gradient separation can be a valuable start to the development of a final HPLC method. Conditions for optimized retention can be estimated prior to the first experimental run (see section 3.1), such that most sample components are partially resolved and some idea of sample complexity can be formed. Furthermore, minor components that elute either early or late are

Figure 4 Easier detection of minor bands (∗) with gradient elution (b) versus isocratic separation (a). Hypothetical chromatograms.

often overlooked during isocratic separation, whereas the presence of such components is much more obvious in a gradient run (see Figure 4 and note peaks A and G marked by an asterisk). Once an initial gradient run has been obtained, it is possible to estimate reliably whether further experiments (and the final method) should be carried out under isocratic or under gradient conditions. Figure 4, which involves a gradient time $t_G = 20$ min (see Figure 3a) can be used to illustrate this procedure. As a first example, assume that only the major peaks B–F are of interest. Next, determine the difference in retention times for the first (B) and last (F) peaks, equal to $14.5 - 11.8 = 2.7$ min. Multiply this by the gradient rate (95% per 20 min $= 4.75\%$ min^{-1}). If the elution range (2.7 min $\times$ 4.75% min^{-1} $= 12.8\%$) is less than 25%, isocratic elution will be preferred. If this ratio is larger, then gradient elution generally will be advantageous. In this latter example, isocratic elution is recommended. Alternatively, assume that peaks A–G are of interest. For this case, the retention time difference is $16.3 - 6.3 = 10$ min, and the elution range is 10 min $\times$ 4.75% min^{-1} $= 47.5\%$. For the separation of peaks A–G, gradient elution would be a better choice. For samples where isocratic elution is preferred, the initial gradient run can also provide an estimate of isocratic % B for good sample retention ($1 < k < 10$),[6] thus avoiding a need for trial-and-error adjustments of % B in later runs.

1.3 Linear versus Nonlinear Gradients

Figure 3(a–e) illustrates different gradient shapes that modern equipment is able to deliver, as desired by the user. While linear gradients (Figure 3a) are generally preferred, nonlinear gradients can sometimes reduce separation time, improve sample resolution, and/or increase detection sensitivity. Segmented gradients (as in Figure 3d) are generally preferred with respect to other nonlinear gradient shapes (e.g. Figure 3b and c), because they are easier to optimize for a given sample. A common application of segmented gradients is the use of a very steep end-segment (or a step gradient) to 100% B in order to clean the column before the next injection. Less often, segmented gradients are useful in optimizing different parts of the chromatogram (see section 3.2). Thus, early peaks may prefer a steep gradient, while later peaks are better separated with a flat gradient (or vice versa).

1.4 Equipment Used for Gradient Elution

An HPLC system equipped for gradient elution must provide a means for creating gradients of various shapes, as in Figure 3. Typically, this is achieved by an electronic controller that varies the flow of two solvents A and B into a mixing chamber (“gradient mixer”), from which the mobile phase A–B passes into the column. This is illustrated in Figure 5(a) for a so-called “high pressure” mixing system. Solvents A and B are contained in reservoirs that feed separate pumps. The electronic controller can be programmed by the user to specify the desired gradient in terms of starting % B, final % B, gradient time t_G (or % B min^{-1}), and shape. The total flow rate is usually maintained constant during the gradient. Once the gradient is programmed and separation is begun, the controller determines the relative flow of solvents A and B to the mixer as a function of time. This in turn generates gradients as in Figure 3(a–e). Typically, sample injection initiates the start of the gradient.

There are two general designs of gradient equipment, corresponding to the high-pressure mixing system of Figure 5(a), or the low-pressure mixing system of Figure 5(b). In the latter system, the gradient is formed before the pump and only one pump is required to deliver the gradient to the column. High- and low-pressure systems are each widely used and are equally capable of reliable operation.

High-pressure mixing systems have a simple design, with the flow rate of the two pumps varying to provide the desired proportion of solvents A and B. Mixing takes place on the high-pressure side of the pump, minimizing outgassing problems (see section 4.3) and usually giving a smaller dwell volume (see section 4.2).

Low-pressure mixing systems require only one pump and may accommodate up to four solvents in many designs. Because solvents are mixed at atmospheric pressure, outgassing can compromise pump reliability

Figure 5 Equipment for gradient elution. (a) High-pressure mixing, (b) low-pressure mixing. (Reprinted with permission from Poole and Schuette.[7])

and the passage of the mixed solvents through the pump usually results in a larger dwell volume.

2 THEORY

Gradient elution involves additional experimental options when compared with isocratic separation, and for this reason is a more complicated technique to use and to understand. Fortunately, it is possible to describe gradient elution in virtually the same way as isocratic elution. Since most chromatographers are familiar with isocratic elution, it is therefore possible to achieve a similar understanding of gradient elution with little extra effort. In the following discussion, mobile phase composition as defined by % B will also be referred to as ϕ, the volume-fraction of B in the mobile phase A–B; $\phi = 0.01 \times (\%\ \mathrm{B})$.

2.1 Band Migration During Gradient Elution

In gradient elution the sample is typically (but not always) strongly retained at the beginning of the gradient, i.e. as for isocratic elution with the starting mobile phase. As the mobile phase becomes stronger during the gradient (larger ϕ or % B), sample retention decreases (as in Figure 2) and eventually the least-retained band X in the sample begins to migrate through the column. This process is illustrated in Figure 6 for the first (X) and last (Z) bands in the chromatogram. The solid curve labeled "X" shown in Figure 6(a) shows the migration of the band from the column inlet to outlet during the gradient. The accompanying dashed curve describes the instantaneous isocratic retention k during the gradient, i.e. the value of k for a mobile phase composition ϕ at the same location in the column occupied by band X. Because ϕ increases during the gradient, k decreases, and band migration accelerates as a function of time. At some time t_x (equal to the retention time t_R of the band), compound X leaves the column and appears as the first band in the chromatogram.

In gradient elution it is possible to define an average retention factor k^*, corresponding to an isocratic value k. Likewise, it is possible to define an average mobile phase composition $\phi = \phi^*$. Values of k^* and ϕ^* correspond to values of k and ϕ when the band has migrated halfway through the column ("band migration" = 0.5 in Figure 6). In the example of Figure 6, $k^* = 2$ for band X. Other sample components will migrate through the column at later times, as illustrated by the last band Z

Figure 6 Band migration during gradient elution. (a) Solid curve, band migration; dashed curve, instantaneous value of k. (b) Resulting chromatogram showing first (X) and last (Z) peaks. See text for details. (Reprinted with permission from Snyder et al.[6])

in Figure 6. These later-eluting bands can be thought of as remaining stationary at the head of the column (very large isocratic k) until a sufficiently strong mobile phase arrives, causing them to move through the column. Because of the similar migration pattern (solid curves in Figure 6) for different sample components during gradient elution, values of k^* generally will be approximately equal for each band and therefore bandwidths in gradient elution tend to be similar for all sample components (see Figure 2b).

2.2 Linear Solvent Strength Model

Reversed-phase retention usually can be approximated by Equation (1)

$$\log k = \log k_w - S\phi \tag{1}$$

Here, $\log k$ varies linearly with mobile phase composition ϕ; k_w refers to the extrapolated value of k for water as mobile phase ($\phi = 0$), and S is a constant for a particular sample compound when only ϕ varies. If a linear gradient is chosen (as in Figure 3a), Equation (2) applies

$$\phi = \phi_o + (\phi_f - \phi_o)\frac{t}{t_G} \tag{2}$$

where ϕ_o and ϕ_f refer to the initial and final ϕ values, and t is time. Combination of Equations (1) and (2) then gives Equation (3)

$$\log k = (\log k_w - S\phi_o) - \frac{S(\phi_f - \phi_o)}{t_G}t = A - Bt \tag{3}$$

Here, A and B are constants for a sample compound, and $\log k$ varies linearly with time t. We will refer to gradient separations which can be approximated by Equation (3) as linear solvent strength (LSS) gradients. Gradients of this type can be described in the same terms used for isocratic elution, and for this reason LSS gradients provide a convenient basis for understanding gradient separations. The LSS model can also provide a more qualitative (but still useful) description of other HPLC methods, e.g. ion-exchange or normal-phase chromatography. For a more detailed discussion of LSS theory, see Snyder and Dolan.[8]

2.3 Retention and Bandwidth in Gradient Elution

The average retention of a band in reversed-phase gradient elution is given for LSS gradients as Equation (4)

$$k^* = \frac{0.87 t_G F}{V_m \Delta\phi S} \tag{4}$$

where F is flow rate, V_m is the column dead volume, and $\Delta\phi$ equals $(\phi_f - \phi_o)$, the change in ϕ during the gradient. For reversed-phase HPLC, an average value of $S \approx 4$ can be assumed for compounds with molecular weights < 500 Da.[9] Just as in isocratic elution it is desirable for $1 < k < 10$, so in gradient elution it is advantageous for $1 < k^* < 10$. However, in gradient elution with a linear gradient the value of k^* will be similar for every sample band and an intermediate value of k^*, e.g. $k^* = 5$, is a good initial choice.

Prior to any experimental runs, preferred starting conditions for a gradient separation can be selected, such that $k^* \approx 5$. As an example, assume that a column and flow rate are selected for the same reasons as in isocratic separation (to provide acceptable column back-pressure and a reasonable run time), e.g. a 15×0.46 cm C_{18} column at 2.0 mL min^{-1}. For columns with an internal diameter of 0.46 cm, the column dead volume V_m can be approximated by 0.1 times the column length in centimeters, or 1.5 mL in this example. Similarly, for a sample that has not previously been separated by HPLC, it is wise to use a full-range gradient (e.g. 0–100% B) so that $\Delta\phi = 1.0$. Full-range gradients can provide reasonable separation for samples that are either weakly or strongly retained. Referring to Equation (4), the only variable so far not specified is gradient time t_G; Equation (4), with $S \approx 4$, can be rearranged to solve for the necessary gradient time to achieve a value of $k^* = 5$, Equation (5):

$$t_G \approx \frac{20\, V_m \Delta\phi}{F} \tag{5}$$

For the column ($V_m = 1.5$ mL), flow rate (2.0 mL min^{-1}), and gradient range ($\Delta\phi = 1$) assumed in this example, a gradient time of 15 min should result in $k^* \approx 5$. This would be a good choice of conditions for the first experiment in HPLC method development.

Baseline bandwidth, W, in isocratic separation is given from the definition of column plate number, N, as, Equation (6)

$$W = \left(\frac{16}{N}\right)^{1/2} t_R = 4t_o \frac{k+1}{N^{-1/2}} \tag{6}$$

For gradient separations, a similar equation can be derived from the LSS model,[8] where k in Equation (6) is replaced by the value of k in gradient elution when the band leaves the column: $k^*/2$. This gives for gradient elution, Equation (7)

$$W = 4t_o \frac{(k^*/2)+1}{N^{-1/2}} \tag{7}$$

Thus, bandwidth in gradient elution is very similar to that in isocratic separation, except that for ''corresponding conditions'' ($k = k^*$), bandwidths in gradient elution are predicted to be smaller. However, Equation (7)

ignores the fact that a gradient tends to compress the sample band further, because the band tail leaves the column in a higher % B than the band front. On the other hand, this effect (which tends to sharpen bands in gradient versus isocratic elution) is compensated by another phenomenon, ''anomalous band broadening'' as discussed by Snyder and Dolan.[8] As a result, Equation (6) is in most cases an adequate approximation for bandwidth in gradient elution.

2.4 Resolution in Gradient Elution

Resolution in gradient elution is conveniently expressed by a relationship that can be derived from the LSS model, Equation (8):

$$R_s = \frac{1}{4}(\alpha - 1)N^{1/2}\frac{k^*}{k^* + 1} \qquad (8)$$

Equation (8) is of identical form as for isocratic elution (where k replaces k^* in Equation 8). Here, α is the separation factor, and both α and N in Equation (8) are average quantities measured when the band is at the column midpoint. Equation (8) is useful for gradient elution method development, where separation can be systematically improved by successive changes in sample retention, k^*, separation selectivity as measured by α, and column efficiency N. This is further illustrated in section 3.

3 SELECTING CONDITIONS FOR GRADIENT ELUTION

HPLC method development consists of experiments that can be used to select conditions for adequate separation, a process that is sometimes referred to as *optimizing* the separation. A detailed discussion of method development for gradient elution is given by Snyder et al.,[6] where it is shown that essentially the same procedure can be used for both gradient and isocratic methods. Sample retention as measured by k^* or k is the most easily optimized and usually is adjusted first. Separation selectivity as measured by α is often of critical importance and usually is considered next. Changes in selectivity (α) are essential whenever bands overlap in the chromatogram. Changes in column efficiency (N) are achieved by varying column length, particle size, and flow rate, and usually are carried out after optimizing sample retention k^* and separation selectivity α.

3.1 Effects of Gradient Steepness, Range, and Shape

Changes in gradient steepness, range, and shape mainly affect sample retention k^*.

Figure 7 Effect of gradient time (t_G) and steepness (% B min^{-1}) on separation. Herbicides sample, 25 × 0.46-cm C_{18} column, methanol–water gradients. (a) 0–100% B in 5 min, 20% min^{-1}, $k^* = 0.7$; (b) 0–100% B in 20 min, 5% min^{-1}, $k^* = 3$; (c) 0–100% in 100 min, 1% min^{-1}, $k^* = 14$. (Reprinted with permission from Snyder et al.[6])

3.1.1 Gradient Steepness

Gradient steepness is defined as the change in % B per minute during the gradient (or $\Delta\phi/t_G$). From Equation (4), k^* is seen to vary with $t_G/\Delta\phi$, i.e. inversely as gradient steepness. As k increases in isocratic separation (Figure 2), overall separation (R_s) is seen to improve, run time increases, and bands become wider so that detection sensitivity decreases. Exactly the same results are expected in gradient elution when k^* increases. An increase in k^* is most conveniently effected by increasing gradient time, t_G, equivalent to decreasing gradient steepness. This is illustrated in Figure 7 for the separation of a herbicide sample, where the gradient time is changed from 5 min (a) to 20 min (b) and 100 min (c), corresponding to a change in k^* from 0.7 to 3 to 14. It is apparent in Figure 7 that sample resolution increases from Figure 7(a) to Figure 7(c); this is better seen for the

three bands at the end of the chromatogram (bracket and arrow). For the five-minute gradient Figure 7(a), the three bands overlap completely. When the gradient time is increased to 20 min Figure 7(b), the last band is separated to baseline, and the other two bands are partly resolved. For the 100-minute gradient Figure 7(c), all three bands are adequately resolved. At the same time, when gradient time is increased, all bands (except the solvent peak at 1.5 min) broaden and, because band area is constant, corresponding peak heights decrease (reduced detection sensitivity).

We can summarize Figure 7 as follows. Resolution is inadequate for the five-minute gradient in Figure 7(a), where $k^* = 0.7$; similarly, for the 100-minute gradient of Figure 7(c), where $k^* = 14$, run time is excessive and detection sensitivity is poor. These results are typical of separations where $k^* < 1$ or $k^* > 10$. In general, an intermediate gradient time will be optimum, and the 20-minute gradient of Figure 7(b), for which $k^* = 3$, comes close in this respect. However, three band pairs are poorly resolved, so an increase in gradient time to 50 min ($k^* = 7$) is a better choice, as seen in Figure 8(a). Although bands 7/8 are separated with marginal resolution ($R_s = 1.1$), this is a reasonable result at this stage in method development. It should be possible to improve the separation of bands 7/8 by a later change in separation selectivity (see section 3.2).

3.1.2 *Gradient Range*

Once an optimum value of gradient steepness is determined as in Figure 8(a) (2% B min^{-1}), a change in gradient range (values of ϕ_o and ϕ_f) is the next step. The primary goal of changing the initial and final % B of the gradient is to save time. Thus, in the separation of Figure 8(a), there is an empty space in the chromatogram (devoid of peaks) between 4 and 19 min which represents wasted time. This wasted time can be reduced by an increase in the initial value of % B (ϕ_o). Figure 8(b) shows the result of an increase in initial % B from 0 to 40%. When changing the gradient range in order to reduce run time, it is important to keep gradient steepness (2% B min^{-1} in this example) constant to keep k^* constant. So gradient time is reduced from 50 to 30 min in the example of Figure 8(b). The overall appearance of the chromatogram is nearly identical between the two runs of Figure 8(a) and (b), which is typical when changing gradient range while maintaining gradient steepness constant. A slight loss of resolution (from $R_s = 1.1$ to 1.0) is seen for critical band-pair 7/8, but this is acceptable. The result of a further increase in initial % B to 60% is shown in Figure 8(c), with a further decrease in gradient time to 20 min. However, now the initial % B of the gradient is too large; early bands are pushed together with a serious loss

Figure 8 Effect of initial % B (ϕ_o) on gradient separation. Herbicides sample, conditions (other than initial % B) as in Figure 7. (a) 0–100% B in 50 min (2% min^{-1}), (b) 40–100% B in 30 min (2% min^{-1}), (c) 60–100% B in 20 min (2% min^{-1}), (d) 50–100% B in 25 min (optimum). (Reprinted with permission from Snyder et al.[6])

of resolution ($R_s = 0.7$). A more reasonable compromise is shown in Figure 8(d), where 50% B as initial mobile phase results in marginal resolution ($R_s = 0.9$), but run time is reduced to only 25 min. The choice of Figure 8(d) as ''best'' assumes that later changes in separation selectivity will be able to restore the resolution of bands 7/8 to an acceptable value (e.g. $R_s > 1.5$).

The last band in Figure 8(d) leaves the column before the gradient has ended, which represents a further opportunity to reduce wasted time and shorten the run time. This is illustrated for the same separation in Figure 9(a), where the end of the gradient is indicated by an arrow. A general goal in selecting the final % B for the

Figure 9 Effect of final % B (ϕ_f) on gradient separation. Herbicides sample, conditions (other than final % B and gradient time) as in Figure 8(d). (a) 50–100% B in 25 min (2% min^{-1}), (b) 50–80% B in 15 min (2% min^{-1}), (c) 50–70% B in 10 min (2% min^{-1}), (d) 50–60% B in 5 min (2% min^{-1}). (Reprinted with permission from Snyder et al.[6])

gradient is to terminate the gradient at the time the last band is eluted. In the present case, the last band elutes when the mobile phase leaving the column is 80% B, suggesting a gradient range of 50–80% B and a gradient time of 15 min. This separation is shown in Figure 9(b). At this point, the run time of the original gradient (0–100% B in 50 min) has been shortened from 43 min (Figure 8a) to 18 min (Figure 9b), with only a minor loss in resolution. If the final % B is further reduced to 70% (Figure 9c) or 60% (Figure 9d), the result is an increase in run time and a broadening of later bands with loss in detection sensitivity, as a result of elution of bands after the gradient ends. These bands show isocratic retention behavior, as seen by broader peaks as retention increases. Elution of

Figure 10 Gradient separations of a 22-component peptide sample (tryptic digest of recombinant human growth hormone); acetonitrile–water gradients with 0.1% trifluoroacetic acid (TFA); 1.0 mL min^{-1}; 40 °C. (a) 0–47% B in 74 min; (b) 2/32/47% B in 0/48/56 min. (Reprinted with permission from Snyder et al.[6])

sample bands after the gradient is always disadvantageous and should be avoided where possible.

3.1.3 Gradient Shape

Linear gradients are generally preferred and should always be tried first. After gradient retention has been adjusted as in Figures 7–9, a change in gradient shape can sometimes be used to improve the separation further.[6] A typical example is shown in Figure 10, where the linear gradient in Figure 10(a) results in a rather long run time, and later bands are widely spaced in the chromatogram (i.e. are overseparated). In cases like this, an increase in gradient steepness toward the end of the chromatogram can result in faster elution of later bands without an unacceptable decrease in resolution. This is illustrated in Figure 10(b), where run time has been reduced from 74 to 60 min, without compromising the separation of later bands. Because gradient steepness is the same in Figure 10(a) and (b) prior to 48 min (the breakpoint in the gradient of Figure 10b), the separation of peaks (#1–15) eluting before 48 min is identical in Figure 10(a) and (b).

A change in gradient steepness also can be used to improve sample resolution, when separation selectivity varies with gradient steepness. This is illustrated in the example of Figure 11, discussed further in the following section.

3.2 Control of Band Spacing

After gradient retention has been optimized as in Figures 7–9, the next step is a change in separation selectivity as a means of avoiding overlapping bands. With only minor changes, the same approach can be used in both gradient and isocratic elution in order to optimize selectivity and band spacing. Table 1 lists some of the variables that are commonly used to change band spacing. Because there are several ways to change selectivity and because improvements in band spacing are unpredictable, optimizing band spacing (α) usually requires more effort than optimizing either retention (k^*) or column efficiency (N).

Some variables (first column in Table 1) affect every kind of sample, whereas other variables (second column of Table 1) only affect samples that are ionizable, i.e. containing acids and/or bases. The ability of a change in the variables of Table 1 to change band spacing (and improve resolution) decreases generally in going down each list;[10] i.e. B-solvent type > column type > gradient steepness > temperature, and pH > ion-pairing > buffer or additive concentration. Also, ionizable samples generally show larger changes in band spacing when a particular variable is changed. On the other hand, the use of gradient steepness and temperature to change selectivity is particularly convenient and is free from

Figure 11 Gradient separation of a polycyclic aromatic hydrocarbon (PAH) sample as a function of gradient steepness. Sample: 16 compounds ranging from naphthalene to indenopyrene. Conditions: 15 × 0.46-cm Supelco LC-PAH column; acetonitrile–water gradients; 2.0 mL min^{-1}; 35 °C. (a) 40–100% B in 7 min, $R_s = 1.0$; (b) 40–100% B in 20 min, $R_s = 0.9$; (c) 40–100% B in 12.5 min, $R_s = 1.4$; (d) 40/50/100% B in 0/45/8.7 min, $R_s = 1.7$. (Reprinted with permission from Snyder et al.[6])

various problems that can arise during the control of selectivity.[10] For this reason, the simultaneous variation of both temperature and gradient steepness is especially useful for controlling selectivity during gradient elution method development (see section 3.4).

Changes in gradient steepness, as in Figure 7, are usually the first step in gradient method development. During these experiments, changes in band spacing may be observed which can be exploited for optimizing selectivity. This is illustrated in Figure 11 for the separation of a mixture of 16 PAHs of environmental concern.

Table 1 Separation variables commonly used to change band spacing (α)

Any sample	Ionizable samples
B-solvent type	Mobile phase pH
Column type	Ion-pairing
Fine-tune t_G (vary k^*)	Buffer or additives concentration
Temperature	

Figure 11(a) and (b) shows separations for gradient times of 7 and 20 min. In the steeper gradient of Figure 11(a), band-pair 3/4 is ''critical'', i.e. is the least resolved. In the shallower gradient of Figure 11(b), band-pair 14/15 is critical. This suggests that an intermediate gradient time will provide a better overall separation, as is seen in Figure 11(c) for a gradient time of 12.5 min. Because early bands 3/4 prefer a shallower gradient, while later bands 14/15 prefer a steeper gradient, an even better separation is predicted for a segmented gradient which is shallow initially and steep at the end. This is confirmed in the separation of Figure 11(d), where all bands are separated to baseline ($R_s \geq 1.7$). This example illustrates one of the (few) unique differences between isocratic and gradient elution. In isocratic elution, because experimental conditions cannot be changed during the separation, maximum resolution for the critical band-pair(s) usually represents a compromise for the overall sample, as in Figure 11(c) for this gradient separation. However, because conditions can be changed during gradient elution, it is possible to optimize conditions separately for early-eluting with respect to late-eluting bands.

Figure 12 shows a similar change in band spacing for the separation of a mixture of substituted phenols. The separation in Figure 12(a) with an acetonitrile–water gradient provides baseline separation of all compounds except bands 8/9. A change in B-solvent from acetonitrile to methanol in Figure 12(b) results in the separation of band-pair 8/9, but with some loss in resolution of bands 2 and 3. In Figure 12(c), the use of a gradient that begins with 20% acetonitrile–water and ends with 100% methanol provides the best overall separation, similar to the example of Figure 11(d).

A final example of selectivity control in gradient elution is shown in Figure 13. Here, five synthetic peptides are separated with acetonitrile–water gradients, with a variable amount of TFA added to the mobile phase as a combined buffer and ion-pairing agent. A change in the concentration of an ion-pairing agent can provide very large changes in band spacing, when the sample contains compounds whose molecular charge varies widely (as in the present case, where the band numbering in Figure 13 indicates the net positive charge on each compound). An examination of these six chromatograms shows that the addition of 0.05% TFA to the mobile phase provides the

Figure 12 Effect of B-solvent on separation of a mixture of phenols. Conditions: 30 × 0.42-cm C_{18} column; gradients as in figure; 1.0 mL min^{-1}; ambient. See text for details. (Reprinted from Jandera et al.[11] *J. Chromatogr.*, Copyright (1981) with permission of Elsevier Science.)

best overall separation. Because bands 1 and 2a are the critical pair in this chromatogram, it can be predicted that a slight increase in TFA (to 0.06 or 0.07%) should provide an even better resolution for the critical band pair.

Figure 13 Separation of basic peptides as a function of TFA concentration. Conditions: 25 × 0.46-cm C_{18} column; A-solvent, water plus indicated %-TFA; B-solvent, acetonitrile plus indicated %-TFA; gradient from 0% B at 1% min^{-1}; 1.0 mL min^{-1}; 26 °C. 3.3 Effects of Column Dimensions, Particle Size and Flow Rate

Varying the column plate number N in either isocratic or gradient method development is usually best delayed until after retention (k or k^*) and selectivity (α) have been

optimized. At this point in method development, N can be increased for an increase in sample resolution. Also, since an increase in N usually requires a longer run time, a decrease in N can be used to save separation time, if sample resolution is greater than necessary. A change in N can be achieved by a change in "column conditions": column length L, particle size of the column packing d_p, or flow rate F. An increase in N usually results from an increase in L or a decrease in d_p or F. (Changes in N with F are more pronounced for larger (e.g. 10-μm d_p) particle packings, and may be of little practical benefit for 3–5-μm d_p materials.)

In isocratic separation, a change in L or F has no effect on values of k or α, so optimizing column conditions can be carried out independently of changes in k or α. That is, further improvements in an isocratic separation by varying L or F can be made without worrying about any corresponding changes in k or α. Because k^* in gradient elution depends on both column size (V_m) and F (Equation 4), changes in k^* and α can result when varying L or F. This is illustrated in Figure 14, for the separation of a peptide sample (tryptic digest of the protein myoglobin). Entire chromatograms are shown in Figure 14(a) for two different flow rates (0.5 and 1.5 mL min^{-1}), other conditions being the same. Expanded portions of each chromatogram (brackets, arrows) are reproduced in Figure 14(b) for easier visibility. It is seen in Figure 14(b) that the change in flow rate from 0.5 to 1.5 mL min^{-1} results in major changes in band spacing: coelution of bands 5 and 5a at 1.5 mL min^{-1}, coelution of bands 6 and 6a at 0.5 mL min^{-1}, and a reversal of the retention of bands 6b and 7. Changes in selectivity such as this, as a result of varying F or L, would not occur in isocratic separation.

Figure 14 Effect of flow rate on selectivity in gradient elution. Sample: peptides from tryptic digest of myoglobin. Conditions: 8 × 0.62-cm C_8 column; 10–70% acetonitrile–water gradient in 60 min (0.1% TFA added to each solvent); 35 °C; flow rates as indicated. (a) Entire chromatograms; (b) expansions of parts of each chromatogram from (a) (see arrows). (Reprinted with permission from Glajch et al.[13])

Because a change in column conditions generally is delayed until after band spacing has been optimized, further changes in band spacing when optimizing N are undesirable. Changes in α similar to those of Figure 14 can be avoided when changing column conditions by maintaining k^* constant. Referring to Equation (4) (and noting that V_m is proportional to L), if k^* is to remain constant while varying L or F, then it is necessary to maintain ($t_G F/L$) constant. This can be achieved by varying gradient time in inverse proportion to F and in direct proportion to L.

3.4 Computer Simulation

The theory of reversed-phase gradient elution has now been developed to a point where it is possible to predict retention times, t_R, and bandwidths, W, as a function of experimental conditions, when the parameters of Equation (1) (k_w and S) are known. Thus, Equation (9)

$$t_R = \frac{t_o}{1.15k^*} \log\left(\frac{2k_o}{k^*} + 1\right) + t_o + t_D \qquad (9)$$

Here, t_o is the column dead time, k_o is the value of k at the start of the gradient, and t_D is the equipment hold-up or "dwell" time (see section 4.2). Similar predictions of gradient retention time can be made for ion-exchange separation.[14,15] For the case of reversed-phase gradient elution, two experimental runs suffice to determine k_w and S for each compound in the sample.[8] If these values are entered into computer simulation software (Snyder et al.,[2] and Snyder et al.[6] page 448–452), it is then possible to predict separation for

Table 2 Predictions of gradient separation by means of computer simulation (Snyder et al.[2] and Snyder et al.[6] 448–452). Based on two experimental runs, the changes in conditions listed can be predicted

Gradient time	Column length and diameter
Initial and final % B	Particle size
Gradient shape	Flow rate

various changes in conditions as summarized in Table 2. Thus, a small number of experiments during method development allow the prediction of a large number of separations, leading to the speedy optimization of the various conditions of Table 2. Computer simulation is also useful for studying the general consequences of different changes in conditions, as in the examples (computer simulations) of Figures 7–9.

Computer simulation has recently been extended[16,17] to allow the simultaneous optimization of temperature and gradient steepness, in addition to the other conditions of Table 2. This is illustrated in Figure 15 for the separation of a mixture of 13 commercial herbicides. Predictions of separation as in Figure 15 require four experimental runs, where two different temperatures T and gradient times t_G are used: 30 and 40 °C and 40 and 120 min in this example. Following entry of the resulting data (retention times, band areas, experimental conditions) into the computer simulation program, various predictions as in Table 2 are possible. Usually it is desirable to request a resolution map, which plots critical resolution (for the least resolved band

Figure 15 Computer simulation for the optimization of the separation of 13 herbicides. Conditions: 25 × 0.46-cm C_{18} column, 20–95% acetonitrile–buffer gradients, 1.0 mL min^{-1}. (a) Resolution map; (b) predicted chromatogram for 30 °C and 80-min gradient; (c) experimental chromatogram for conditions of (b). (Reprinted from Dolan et al.[16] *J. Chromatogr.*, Copyright (1998) with permission from Elsevier Science.)

pair) as a function of gradient time and temperature in this example. Figure 15(a) shows the resulting resolution map, with maximum resolution indicated for 34 °C and a 90-min gradient time. The predicted separation is shown in Figure 15(b), and the experimental confirmation of this prediction is given in Figure 15(c). Retention time predictions by means of computer simulation are typically accurate to better than 1%, as in the example of Figure 15.

4 "NONIDEAL" EFFECTS IN GRADIENT ELUTION

Apart from its somewhat greater complexity, as summarized in sections 1–3, gradient elution is subject to some additional problems which are absent (or uncommon) in the case of isocratic elution. The effective use of gradient elution for practical applications requires an awareness of these "non-ideal" effects (see Snyder et al.[6] for further details).

4.1 Nonequilibration of the Column

When the mobile phase is changed in isocratic elution, it is necessary to flush the column with a sufficient volume of the new mobile phase to equilibrate the column. However, once the column is equilibrated, samples can be successively injected without further concern for column equilibration. In the case of gradient elution, the mobile phase at the end of each separation differs from the beginning mobile phase for the next sample injection. This requires that the column be flushed with a sufficient volume of the initial mobile phase to achieve equilibration of the column, prior to injection of the next sample. Although column equilibration typically can be achieved by flushing with 5–10 column volumes of the starting mobile phase, the exact intersample flush volume must be experimentally confirmed for each gradient method. Equilibration volume can be checked by selecting a starting volume (e.g. 5 column volumes) and making a run. Then the equilibration volume is increased (e.g. to 10 column volumes) and the run is repeated. The equilibration volume will be satisfactory when further increases in volume cause no change in sample retention (poor equilibration generally appears as shorter retention times, especially for early eluting peaks). Because of the need for column equilibration between each sample injection, total run time in gradient elution usually is somewhat greater than for isocratic separation. However, extremely fast gradient separations (e.g. 1–2 min run times) are nevertheless possible.[18]

Another practical consequence of column equilibration in gradient elution regards the choice of the initial % B. At very high water content (e.g. >97%), the bonded phase on reversed-phase columns tends to undergo a configuration change or "collapse". Resolvation of the phase following collapse can be slow when compared to normal column equilibration, further extending the turnaround time for routine operation. The magnitude of this equilibration problem varies with the stationary phase and sample type. It is prudent to use ≥5% B as the starting solvent for gradient elution to avoid this phenomenon. Thus, most workers prefer 5–100% B gradients over 0–100% B.

4.2 Gradient Delay and Rounding

The design of the equipment used for gradient elution (Figure 5) results in some distortion of the gradient delivered to the column, as illustrated in Figure 3(f). Thus, following the combination of A and B solvents, the resulting mobile phase must pass through the gradient mixer, various connecting lines and filters, the autosampler, and (in the case of low-pressure gradient mixing) the pump. As a result of this movement of mobile phase through the system, the gradient will be delayed and to some extent dispersed or rounded. This means that the programmed gradient can differ significantly from the actual gradient. Because these differences are peculiar to each equipment design, gradient methods tend to be less transferable than isocratic methods.

The main effect of equipment differences on separation is usually the result of differences in the hold-up or "dwell" volume, i.e. the volume swept out by the mobile phase as it passes through the mixer onto the column. If the equipment dwell volume is known, it is possible to predict its effect on separation by means of computer simulation (see section 3.4). In most cases, minor changes in gradient conditions (initial % B, gradient steepness) can be used to adjust for differences in dwell volume.

4.3 Equipment and Baseline Problems

The added complexity of the equipment used for gradient elution can create additional problems that are less common or nonexistent with isocratic systems. In practice, however, many workers use the same equipment for isocratic as for gradient separations because of the convenience of on-line mixing. The potential problems outlined here can be overcome, for the most part.

4.3.1 Mobile Phase Outgassing

When organic solvent/water blends are prepared, the resulting mixture usually has a lower capacity for dissolved air than the pure solvents. When solvents are mixed on-line to form the gradient, outgassing can occur. If these bubbles pass through the pump, check-valve failure, pressure fluctuations, and flow variation can occur. Outgassing tends to be more of a problem

for low-pressure mixing systems because the solvents are mixed at (or below) atmospheric pressure. High-pressure mixing tends to compress the air, keeping it in solution, so fewer bubble problems are experienced. For both types of equipment, degassing, as with helium sparging, will give more reliable operation.

Sometimes air bubbles are generated when the mobile phase returns to atmospheric pressure at the end of the column. If these bubbles pass through the detector, baseline disturbances result. In addition to mobile phase degassing, the use of a back-pressure regulator after the detector usually will alleviate detector bubble problems.

4.3.2 Proportioning Problems

The actual gradient reaching the column differs from that programmed into the system controller. As illustrated in Figure 3(f), rounding at the ends of the gradient occurs because of the washout characteristics of the equipment. Further distortion of the gradient can occur if the equipment is not operating properly. An easy way to check this is to place a UV (ultraviolet)-absorbing solute in the B-reservoir and run a gradient with a short piece of tubing replacing the column. For example, water can be used for the A solvent and 0.1% acetone in water as the B solvent, with a 0–100% B gradient run over 20 min. If the gradient is straight in the middle, as in Figure 3(f), the equipment appears to be operating properly. If the gradient is bowed or an offset is observed mid-gradient, the system needs to be serviced.

Proportioning accuracy can be checked by programming a series of isocratic steps, as in Figure 3(e), for example 10% steps over a 0–100% B range, using the acetone–water mobile phase. The steps should approach stair steps and be even in size, as in Figure 16(b). If uneven or distorted steps are observed, as in Figure 16(a), equipment service is required. Most manufacturers specify proportioning accuracy of ±0.5–1.0% B; from a practical standpoint, ±1.0% (as in Figure 16b) is satisfactory if the steps are even and well-shaped.

4.3.3 Baseline Drift

Baseline drift in gradient elution is caused by changes in temperature or mobile phase absorbance. Temperature drift should not be a problem if the column is operated in a column oven – this is a wise choice for isocratic methods as well, because retention and selectivity are influenced by temperature.

Baseline drift in temperature-controlled systems may be observed when the A and B solvents have different UV absorbance (assuming UV detection). This is illustrated in Figure 17. Two general trends are observed. First, the organic solvents used for reversed-phase usually have more absorbance than water and the absorbance

Figure 16 Sample results for step test of pump proportioning accuracy for (a) poor pump performance and (b) acceptable pump performance. True % B values shown below each step. See text for details.

varies with the solvent. This is seen for the larger drift with the water–methanol gradient of Figure 17(a) when compared to water–acetonitrile (Figure 17b). Second, as the detection wavelength is reduced, the drift is magnified (compare Figure 17c and 17a). As long as the baseline drift is acceptable (i.e. the baseline stays on-scale), most data systems can successfully integrate peaks, so quantitation should be satisfactory. The lower background absorbance of acetonitrile at low wavelengths (Figure 17a versus Figure 17b) makes it the solvent of choice for low-wavelength gradient applications. An additional advantage of acetonitrile over methanol for gradient elution is its lower viscosity when mixed with water. This results in substantially lower column back pressure, allowing higher flow rates and thus shorter run times.

4.3.4 Baseline Artifacts

One problem with gradient elution that is not experienced with isocratic separation is the presence of background peaks in the gradient. A blank gradient always should

Figure 17 Absorbance profiles for water–organic gradients; wavelengths as noted. (a) Water versus methanol, 215 nm; (b) Water versus acetonitrile, 215 nm; (c) Water versus methanol, 254 nm. (Data from the *HPLC Solvent Reference Manual*.[19] Reproduced courtesy of Mallinckrodt Baker Inc.)

be run prior to a series of samples to determine the magnitude of background peaks. In extreme cases, a blank baseline can appear as shown in Figure 18(a). The observed peaks represent contaminants in the water phase that collect at the head of the column during equilibration and then elute off as if they were sample components when the gradient is run. Use of a better quality of water (Figure 18b) usually will remove most or all of the unwanted peaks. In particularly difficult cases, on-line cleanup[20,21] can be used to advantage. Baseline artifacts will be minimized if HPLC-grade solvents and additives are used.

4.3.5 Buffer Precipitation

Precipitation of buffers in the HPLC system can be a problem, particularly when acetonitrile is used as the organic phase, owing to the poor solubility of buffer salts in high percent-organic solutions. Methanol usually is less of a problem than acetonitrile. Although a buffer may be soluble in a bulk solution, for example in 80% acetonitrile, the mixing characteristics of HPLC systems can cause buffer to be mixed directly with 100% acetonitrile under conditions that will precipitate the buffer. Precipitated buffers are difficult to remove and can foul check valves and column frits. A four-fold approach to check for and avoid such problems usually is successful. First, add the buffer phase drop-wise to the organic phase in a test tube.

Figure 18 Effect of water purity on gradient baselines. Contaminated water (a) and purified water (b). 0–83% acetonitrile–water gradients at 255 nm in 13 min followed by hold; 15 × 0.46-cm C_{18} column, 1.5 mL min^{-1}, 2.3 mL dwell volume.

If any cloudiness is observed when the buffer contacts the organic, it is likely to happen in the HPLC system as well. Second, keep the buffer concentration low (e.g. $\leq$25 mM). Third, premixing the buffer and organic may be helpful. For example, mix 5% buffer in the B reservoir and 5% B-solvent in the A-reservoir. Finally, avoid 100% acetonitrile gradients. Often running a 5–80% acetonitrile–buffer gradient will give the desired gradient conditions without the potential for buffer precipitation as the gradient nears 100% acetonitrile.

LIST OF SYMBOLS

A, B	refers to weak (A) and strong (B) solvents that comprise the mobile phase in reversed-phase HPLC
C_2, C_3, etc.	dimethyl, methylethyl, etc. *o*-phthalates
d_p	column packing particle size (μm)
F	flow rate (mL min^{-1})
k	isocratic retention factor

k^*	gradient retention factor (Equation 4)
k_o	isocratic value of k for a solute at start of gradient
k_w	isocratic value of k for water as mobile phase ($\phi = 0$)
L	column length (cm)
N	column plate number (Equation 6)
R_s	resolution of two adjacent bands, equal to difference in retention times divided by W
S	solute parameter defined in Equation (1)
t	time after start of gradient
t_D	equipment hold-up or ''dwell'' time (min); $t_D = V_D/F$
t_o	column dead time (min); $t_o = V_m/F$
t_G	gradient time (min)
t_R	retention time (min)
V_D	equipment hold-up or ''dwell'' volume (mL)
V_m	column dead volume (mL)
W	baseline bandwidth (min)
α	separation factor, equal to ratio of k-values for two adjacent bands
ϕ	volume fraction of B in mobile phase A–B
ϕ^*	value of ϕ for mobile phase at column mid-point; corresponds to k^*
ϕ_o, ϕ_f	values of ϕ at start and end of gradient

ABBREVIATIONS AND ACRONYMS

HPLC	High-performance Liquid Chromatography
LSS	Linear Solvent Strength
PAH	Polycyclic Aromatic Hydrocarbon
TFA	Trifluoroacetic Acid
UV	Ultraviolet

Ion chromatography (IC), which is an important methodology within high-performance liquid chromatography (HPLC), is a chromatographic separation/detection strategy that is applied to the determination of inorganic and organic analyte anions and cations. The methodology consists of three main components: (1) a low-capacity ion-exchange column, where the separation occurs; (2) a suppressor system, which reduces conductivity due to the mobile phase electrolyte; and (3) a conductivity detector, which is used to detect the analyte ions. Anionic analytes are separated on an anion-exchange column and analyte cations are separated on a cation-exchange column. IC, which is routinely applied in water, environmental, health, and food analysis, is a rapid, sensitive, and accurate method for the trace determination of complex mixtures of analyte ions, particularly analyte anions, where no other method offers similar advantages and scope of application.

Today, the term IC defines a broader group of methodologies applicable to the separation of analyte ions and now also defines the following strategies. Nonsuppressed IC of analyte anions and cations is possible. In addition, analyte ions can be separated with an ion interaction reagent (ion pair reagent) as a mobile phase additive and a reversed stationary phase column rather than an ion-exchange column; this is often called ion interaction chromatography (IIC). Ion exclusion chromatography (IEC), which is a separation of weakly dissociated acid and base analytes on an anion exchanger, is also an important methodology within the field of IC.

1 INTRODUCTION

The concept of what is now called IC was first described by Small, Stevens, and Bauman in 1975.[1] Their paper, which is a classic work in the development of modern liquid column chromatography, describes methodology for the separation of inorganic ions on ion exchangers and detection of the separated ions by conductivity. The keys to their success were twofold. First, a low-capacity ion exchanger was used for the analytical column to effect the separation. Separation occurs because of differences in the way that individual analyte ions and electrolyte ions of similar charge in the mobile phase, which are required for the separation, compete electrostatically for the ion-exchange sites on the ion exchanger. Second, a high-capacity exchanger was used as a suppressor column in series following the analytical column to reduce the effects of mobile phase background electrolyte on conductance but still maintain the analyte in the column effluent as an electrolyte so that it could be detected with sensitivity by conductivity. Separations were accomplished at favorable column efficiencies, low detection limits (DLs), and at fast analysis times. Other separation methods or analytical methodologies, including ion-exchange separation procedures, available at that time, did not offer these advantages. The suppression strategy is essentially a form of postcolumn chemistry, that is, the column effluent containing the mobile phase and the analyte are altered so that the system permits conductivity detection of only the analyte with high sensitivity.

In the work of Small et al.[1] mixtures of inorganic anions, such as Cl^-, Br^-, I^-, SO_4^{2-}, and CO_3^{2-}, and cations, such as Na^+, K^+, Rb^+, Cs^+, NH_4^+, Mg^{2+}, and

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

Ca^{2+}, were completely separated on anion and cation exchangers, respectively, in 10–15 min at analyte levels as low as 1 ppm depending on the analyte and the mixture. For example, Na^+ and K^+ were readily determined in urine, blood serum, and fruit juices while anions were determined in treated and untreated water. Often the samples could be handled in a dilute and shoot strategy, that is, the sample is diluted and an aliquot of this solution is introduced into the column for the separation. Thus, the sample matrix did not have to be removed from the sample prior to analysis. It was also possible through pH control to separate simple organic amines as cations and organic acids as anions. For the first time mixtures of simple inorganic and organic anions and cations could be separated and determined quickly, often in minutes, and at trace to ultratrace levels often in parts per million to sub-parts per million quantities.

Small et al.[1] referred to the methodology as ''Conductive Chromatography''. However, as the significance of this work became recognized and was commercially developed this separation methodology quickly became known as IC. The introduction and subsequent development of IC is of tremendous practical consequence in quantitative analytical chemistry and applications of liquid column chromatography. This is illustrated by Figure 1(a) and 1(b) where ion chromatograms for the separation of test samples of inorganic anions and cations respectively, are listed using current state-of-the-art ion chromatographic mobile-phase conditions, columns, and instrumentation. The chromatography is reproducible and peak area and peak height are proportional to analyte concentration; thus, unknown analysis through calibration is accurate, precise, and sensitive. Furthermore, analysis time is remarkably short. No other analytical method offers such a rapid, accurate, and yet relatively simple procedure for the trace analysis of these kinds of analyte ions.

IC was quickly recognized as one of the foremost methodologies for the determination of simple inorganic and organic analyte ions. It quickly became a routine analytical method that was applied to the determination of water quality and analysis of environmental, biological fluid, food, and industrial samples and related products, by-products, and materials. IC can be performed manually at the bench with individual samples, it can be automated, and it can be used in on-line process monitoring. IC measurements in the field are also possible. Many IC procedures are approved by regulatory agencies, for example the United States Environmental Protection Agency (USEPA), and are invaluable in industrial, health, food, electronic, and environmental analytical laboratories. At present IC procedures often serve as the standard to which other newly developed analytical methodology is compared particularly when considering

Figure 1 ICs for the separation of anions (a) and cations (b). (a) An aqueous 1.7 mM $NaHCO_3$/1.8 mM Na_2CO_3 mobile phase at 2.0 mL min^{-1} with 50 µL injection of a sample of 3 ppm F^-, 4 ppm Cl^-, 10 ppm NO_2^-, 10 ppm Br^-, 20 ppm NO_3^-, 10 ppm HPO_4^{2-}, and 25 ppm SO_4^{2-}, suppressed conductivity detection, and a latex-based anion exchanger (IonPac AS4A). (b) An aqueous 30 mM HCl mobile phase at 1.0 mL min^{-1} with 50 µL injection of a sample of 5 ppm Li^+, 5 ppm Na^+, 10 ppm NH_4^+, 10 ppm K^+, 20 ppm Rb^+, and 30 ppm Cs^+, suppressed conductivity detection, and a latex-based cation exchanger (Fast Sep Cation 1). (Reproduced by permission of Wiley-VCH from J. Weiss, *Ion Chromatography*, 82 and 174.[2])

the analysis of simple inorganic and organic anions and cations.

The scope of IC as demonstrated by Small et al.[1] has broadened and the modern use of the terminology in chromatography means more than the ion-exchange separation of analyte ions and their detection by conductance following suppression of mobile-phase electrolyte. The following sections, while focusing on suppressed IC and its advances, also briefly introduces other advances in IC, namely improvements in ion-exchange column technology, detection, and ion interaction reagents and advances in nonsuppressed IC, IIC and IEC. A more detailed discussion of the principles and applications of IC, nonsuppressed IC, IIC, and IEC is available in several excellent reference books.[2–5]

Clearly, successful application of IC and related strategies to provide solutions to important separation problems rests on four major factors. For a particular separation problem these are: (1) selection of the correct ion-exchange column based on an understanding of the underlying properties of the exchanger, (2) being aware of the scope of the eluting conditions relative to the analyte mixture and the problem at hand, (3) carrying out a systematic manipulation of the first two factors to establish the required resolution of the analyte ions within the column and to obtain detector compatibility at the desired DL, and (4) handling of the chromatographic data to solve the problem at hand.

2 BASIC PRINCIPLES OF ION EXCHANGE

2.1 Ion-exchange Equilibrium

To understand why analyte ion separations occur in IC it is necessary to understand ion-exchange chromatography or the separation of analyte ions on a column containing an ion exchanger. A typical ion exchanger is an insoluble solid substance containing fixed charge centers (ionogenic groups) and exchangeable counterions of opposite charge associated with the ionogenic groups. These counterions can be exchanged for a stoichiometrically equivalent amount of other ions of the same sign when the ion exchanger is in contact with an electrolyte solution. Cation exchangers exchange cations and anion exchangers exchange anions.

The cation-exchange process, where H^+ and Na^+ are competing for the exchange site by electrostatic attraction, can be represented by

$$R^-H^+_{(s)} + Na^+_{(aq)} = R^-Na^+_{(s)} + H^+_{(aq)} \qquad (1)$$

In Equation (1) R^- is the solid insoluble exchanger containing a negatively charged ionogenic group, (s) is the solid form, and (aq) is the aqueous form. For anion exchange, where OH^- and Cl^- are competing for the anion-exchange site by electrostatic attraction, the process is represented by Equation (2)

$$R^+OH^-_{(s)} + Cl^-_{(aq)} = R^+Cl^-_{(s)} + OH^-_{(aq)} \qquad (2)$$

In this case R^+ is the solid insoluble exchanger containing a positively charged ionogenic group. Many naturally occurring and synthetic materials are capable of exhibiting ion-exchange properties but those that are of the most interest in IC are ion exchangers that are specially synthesized for IC applications.

2.2 Properties of Ion Exchangers

2.2.1 Ion-exchange Selectivity

The equilibrium constants, K, for reactions (Equations 1 and 2), which are given by expressions (Equations 3 and 4), respectively, are selectivity constants because each specifies the relative preference of the ion exchanger for one ion over the other.

$$K_H^{Na} = \frac{(R^-Na^+)_s[H^+]_{aq}}{(R^-H^+)_s[Na^+]_{aq}} \qquad (3)$$

$$K_{OH}^{Cl} = \frac{(R^+Cl^-)_s[OH^-]_{aq}}{(R^+OH^-)_s[Cl^-]_{aq}} \qquad (4)$$

By designating one ion as a standard, a selectivity scale can be established for other ions of similar charge relative to the standard ion. For cation exchange H^+ is the standard while for anion exchange the standard is usually OH^- or Cl^-. Table 1 lists cation- and anion-exchange selectivities for a typical strong acid cation and strong base anion exchanger, respectively, where the exchanger matrix is polymer based. It should be noted that selectivity will be influenced not only by the ion exchanger ionogenic group but also by the exchanger matrix to which the ionogenic

Table 1 Anion and cation ion exchange selectivities[a]

Anions	Selectivity	Cations	Selectivity
OH^-	0.09	Li^+	0.9
F^-	0.09	H^+	1.0
$C_2H_3O_2^-$	0.17	Na^+	1.5
HCO_2^-	0.22	NH_4^+	2.0
$H_2PO_4^-$	0.25	K^+	2.5
HCO_3^-	0.32	Rb^+	2.6
Cl^-	1.0	Cs^+	2.7
NO_2^-	1.2	Mg^{2+}	2.5
Br^-	2.8	Ca^{2+}	3.9
NO_3^-	3.8	Sr^{2+}	5.0
HSO_4^-	4.1	Zn^{2+}	2.7
Phenolate	5.2	Cu^{2+}	2.9
I^-	8.7	Ni^{2+}	3.0

[a] See Gjerde and Fritz pps. 65 and 66.[4]

group is bound. In general, when all other factors are equal ion exchangers exhibit higher binding (increased selectivities) for multivalent ions, for ions with decreased hydrated radius, and for ions with increased polarizability.

2.2.2 *Reversibility*

Equations (1) and (2) are equilibrium reactions that are stoichiometric and reversible. Typically, equilibrium is reached quickly. Consider Equation (1) where Na^+ and H^+ are competing for the exchanger anionic site. If the exchanger is placed in an aqueous environment and H^+ and Na^+ (and a suitable anion) are present in equal molar quantities, equilibrium is reached according to the selectivity given by the equilibrium constant in Equation (3). On the other hand if the cation exchanger in the H^+ form is put in a column and a Na^+ solution (for example aqueous NaCl) is continuously passed through the column, H^+ will be continuously removed from the column and will be replaced by the Na^+ until all the H^+ has been replaced. When all the H^+ is removed the Na^+ concentration entering the column will equal the Na^+ leaving the column. If the Na^+ solution is washed out of the column and an aqueous HCl solution is now passed through the column, the exchanger will be converted back to the H^+ form. Thus, Equation (1) can be driven in either direction by either a batch or column operation. Furthermore, the equilibrium can be driven by a cation that has a lower selectivity than the other by using the cation at a higher concentration or by continued passage of the cation solution through the column. This is possible because of mass action.

Binding is quantitative and stoichiometric. Selectivity also determines the order of ion removal from the exchanger and corresponds to the ion elution order if several different analyte ions are present. Since the exchange process usually occurs rapidly, column experiments can be carried out efficiently and reproducibly.

2.2.3 *Rate of Ion Exchange*

Equilibrium is reached rapidly because rates of exchange are usually high. Exchange rates are controlled by diffusion within the exchanger particle, if ionogenic groups within the particle are accessible, and by film diffusion at the exchanger particle surface. Physical properties of the exchanger (see section 2.2.6 in the following) and the type of ionogenic group will influence exchange rates. While ion exchangers are available with capacities as high as 3–5 mM g^{-1}, most ion exchangers used in IC have capacities at or below 200 μM g^{-1}.

2.2.4 *Ion-exchange Capacity*

Ion-exchange capacity is defined by the quantity of exchangeable ions per unit amount of ion exchanger. When an ion exchanger is used in a column to bring about analyte separation due to differences in analyte exchange selectivity, only a small portion of the available exchange capacity should be employed to prevent a column analyte mass overload. Exchange capacity is also sensitive to ion-exchanger physical properties (see section 2.2.6 in the following) because these properties influence the accessibility of the exchange sites.

2.2.5 *Ionogenic Group*

Ionogenic groups or ion-exchange sites are classified as being either strong or weak acid or base groups. Strong acid and base groups are highly dissociated and the exchangers containing these groups are like insoluble strong electrolytes. These groups are $-SO_3^-H^+$ and $-NR_3^+OH^-$ and exchange cations and anions, respectively. Common weak acid ionogenic groups are $-CO_2H$, $-PO_3H_2$, aromatic $-OH$, and aromatic $-SH$ while weak base ionogenic groups are $-NH_2$, $-NHR$, and $-NR_2$. These are like insoluble weak electrolytes and their ability to participate in ion exchange as cation and anion exchangers, respectively, depends on dissociation of the group and therefore on their ionization constant and the pH of the environment. The ionogenic groups can be chemically bound to an organic polymer matrix or chemically bound to silica or other oxides.

2.2.6 *Physical Properties*

Ion exchangers developed for IC applications must satisfy the physical properties demanded by modern liquid chromatography (LC) in addition to providing the desired ion-exchange properties. The exchangers must be available as small, physically strong, uniform size, spherical microparticles that can be reproducibly packed into an efficient column.

Ion exchangers based on an organic polymeric matrix will expand and contract when placed in water or a polar solvent. A highly polar medium favors swelling while a less polar environment favors contraction. Both the type of solvent and the presence of an electrolyte and its concentration influence swelling and contraction. Increased cross-linking in the organic polymer matrix increases physical strength, reduces swelling and solubility, and affects the accessibility of the exchanger sites within the organic polymer and therefore the available exchange capacity. Bead fracture can occur because of rapid swelling or contraction of the ion exchanger. Higher cross-linking will reduce bead fracture and increase particle stability. Rapid swelling and contraction can cause discontinuity in the column packing since these processes will occur in the column when solvent and/or electrolyte concentration of the mobile phase are changed abruptly.

Cross-linking, swelling/contraction, and related properties are more specific to organic polymeric ion exchangers and are generally of less concern with pellicular, latex, or silica-based ion exchangers.

The polymerization strategy used to prepare the polymeric-based ion exchanger will also influence its properties. Polymeric ion exchangers can be prepared that are either gel-like or macroporous. The former have low surface areas and are not truly porous. Their porous-like property is obtained only when the polymer is swollen. In contrast the macroporous polymer has a high surface area and has high porosity. This is because it is a spherical particle that is made up of many ultramicrogel particles joined together. Its porosity is therefore not dependent on swelling of the bead but more so on the space that is present between the attached microgel beads.

The organic polymeric, pellicular, latex, and silica-based ion exchangers are commercially available as spherical particles of uniform microparticle size. Bulk lots of the exchangers can be purchased to pack columns in the laboratory. However, commercially packed columns are used most often because they are available commercially and provide excellent column efficiency and reproducibility.

2.2.7 Stability

A useful ion exchanger in IC must withstand the usual rigors of modern LC and mobile phases routinely used in IC. Bead fracture, swelling/contraction, and reactivity towards eluents can cause serious limitations in IC applications. Organic polymeric, pellicular, and latex-based ion exchangers are stable throughout the pH range of 1 to 14. Silica-based ion exchangers, in contrast, are stable within the range of pH 2 to 9. The ionogenic groups are generally stable; however, the $-R_3N^+X^-$ ionogenic group is the least stable particularly when X^- is OH^- and when the exchanger is dry.

2.2.8 Ion-exchanger Matrix

Ion exchangers for IC are organic polymeric, latex, pellicular, or silica-based and the nature of the matrix can have a strong influence on the chromatographic result. Syntheses of these four types of exchangers are briefly described in the next section.

For an ion exchanger with an organic polymeric matrix its composition, cross-linking, and porous or gel-like properties influence the accessibility of the ionogenic groups, the rate of exchange, and compatibility with mixed and/or nonaqueous solvents. The matrix can also interact with nonionic materials, which may be present in the analyte sample, and over time can alter the column performance. Organic analyte ions that are lipophilic may also interact with the matrix through hydrophobic interactions in addition to ion exchange. Pellicular ion exchangers with a polymeric core can exhibit similar properties but to a much lesser degree.

Analyte hydrophobic interactions are not encountered with pellicular ion exchangers with a silica core or silica bonded-phase ion exchangers. However, these exchangers have a limited useful pH range and can have residual silanol (−SiOH) sites. These sites are weakly acidic and will exhibit cation-exchange properties. The latex ion exchangers typically do not exhibit hydrophobic matrix-retention interactions but they can exhibit both anion and cation exchange depending on their synthesis. A more detailed discussion of the properties of ion exchangers is available in several excellent reference books.[6,7]

3 ION EXCHANGERS IN ION CHROMATOGRAPHY

The major types of anion and cation exchangers used in IC are organic polymeric-based, latex-based, and silica bonded-phase exchangers. These exchangers for IC applications are low in exchange capacity, typically less than 200 $\mu eq\ g^{-1}$, and most often have ionogenic sites on the outer particle surface rather than on the interior of the particle.

3.1 Polymeric Ion Exchangers

Most organic polymeric-type ion exchangers are derived from polystyrene–divinylbenzene (PSDVB) copolymers. Other polymer types used are polyvinyl and polymethacrylate polymers.

PSDVB is prepared by reaction of styrene **(1)** and divinylbenzene **(2)** using the appropriate solvent, catalyst, and reaction conditions according to Scheme 1.

The amount of divinylbenzene used in the synthesis determines the amount of cross-linking in the copolymer and influences the exchanger properties as outlined earlier. The anion exchanger, often referred to as a strong base anion exchanger, is prepared by chemically bonding a quaternary ammonium group to the PSDVB copolymer by chloromethylation of the copolymer followed by reaction with a tertiary amine. This is shown in Scheme 2, where the PSDVB copolymer is represented by the benzene ring. While the R groups can be varied, they typically are methyl groups and the anion exchanger is frequently supplied in the Cl^- form rather than in the OH^- form because the latter is less stable particularly when dry.

The cation exchanger, often referred to as a strong acid cation exchanger, is prepared by a sulfonation procedure.

Cross-linked styrene-divinylbenzene copolymer

Scheme 1

Scheme 2

Scheme 3

In this case a $-SO_3^-H^+$ ionogenic group is bound to the PSDVB copolymer as shown in Scheme 3,
where the benzene ring represents the PSDVB copolymer. Usually, commercially available columns packed with the strong acid cation exchanger are supplied in the H^+ or Na^+ form. Both are equally stable forms.

For both the PSDVB strong acid and base cation and anion exchangers for IC the ionogenic groups are primarily located on the surface of the spherical copolymer beads. For this reason ion-exchange capacity is low but mass transfer for exchange is more favorable. High-capacity ion exchangers, where exchange groups are located on the surface and within the bead, are commercially available. These are usually not used in IC but are useful for IEC. The surface-covered exchangers are preferred because of better exchange kinetics and a more rapid attainment of equilibrium. Other kinds of ionogenic groups exhibiting ion-exchange properties have been prepared but are not necessarily available with an ion-exchange capacity suitable for IC. Several of these are listed in Table 2. It is important to note that all of these have weak acid or base properties and dissociation of the groups, and therefore the ion-exchange properties are pH dependent. The strong acid and base ion exchangers in contrast are highly dissociated like strong insoluble, electrolytes and will exhibit ion-exchange properties throughout the pH range.

Table 2 Common ionogenic groups

Strong acid	Weak acid
$-SO_3^-H^+$[a]	$-CO_2H$,[a] $-PO_3H_2$,[a] phenolic-OH
Strong base	Weak base[a]
$-NR_3^+OH^-$[a]	$-NH_2$, $-NRH$, $-NR_2$

[a] Commercially available for IC.

Ion exchangers that contain the PSDVB matrix will swell in polar solvents and in the presence of electrolyte. Sharp changes in their concentrations can cause rapid and excessive swelling or contracting and can lead to bead fracture. The PSDVB-type exchangers that are of the gel type owing to the polymerization procedure, will typically contain 2–16% divinylbenzene as the cross-linking agent to inhibit swelling/contracting. This gel-type PSDVB, however, is not truly porous-like as a sponge and its porous-like property results from expansion (or contraction) between the copolymer chains. The gel-type ion exchanger, thus, will have an apparent porosity and surface area which are typically very low even when swollen, that is, dependent on the extent of the bead swelling.

A macroporous (also called porous, isoporous, or macroreticular) PSDVB copolymeric-based ion exchanger can be made via modifications in the polymerization strategy. The copolymer for the ion exchanger is still derived from styrene and divinylbenzene, (see Scheme 1) is highly cross-linked ($\gg$16%), and yields a network of submicrosphere gel beads joined together to form a larger, spherical, single bead. The high porosity and surface area, which are much less dependent on bead swelling/contraction, are more permanent because the interstitial spaces between the microgel beads are largely responsible for the porosity. Pore diameters and surface area can exceed 10 nm and 100 $m^2\,g^{-1}$, respectively. The gel-type-derived ion exchanger, in contrast, has only a fraction of this porosity and surface area depending on swelling/contraction. The macroporous-based ion exchangers are physically strong and have favorable ion-exchange rates and mass transfer provided exchange capacity is on the surface particularly when mixed solvents are used. Macroporous ion exchangers with high ion-exchange capacities can be made but the macroporous ion exchangers usually used in IC are low capacity.

3.2 Latex-based Ion Exchangers

Latex-based anion and cation exchangers for IC applications are commercially available. These are pellicular in nature, that is, the ionogenic groups are primarily located on the outer surface of the particle.[2] For the anion exchanger a surface-sulfonated PSDVB particle is the matrix and this is covered by aminated latex microparticles (0.1 μm) which are held to the core primarily by electrostatic forces and to a lesser extent by van der Waals forces. This general structure of the latex anion exchanger is shown in Figure 2(a). The quaternary ammonium groups are in large excess compared to the sulfonic acid groups and the net effect is that anion exchange occurs at the bead surface.

The cation latex-based ion exchangers can be prepared in a similar fashion except that the PSDVB copolymeric surface is first aminated and this is subsequently covered with sulfonated latex microparticles. Since the sulfonated groups are in excess, it functions as a cation exchanger. This type of latex-based cation exchanger, however, suffers from poor reproducibility and chemical stability. A more reliable latex-based cation exchanger is prepared by taking a sulfonated PSDVB particle, coating it with aminated latex microparticles as an inner layer and coating this layer with a layer of sulfonated latex microparticles. A typical structure for the cation latex-based exchanger is shown in Figure 2(b). In this case the sulfonated groups on the outer layer due to the sulfonated latex microparticles are in excess and cation exchange occurs at this sulfonated surface.

Properties of the two exchangers can be altered by changes in the matrix and the ratio of the aminated or the sulfonated latex to the pellicular sulfonated or aminated groups. In general, cation and anion retention order is the same for both the PSDVB and latex-based strong-acid and base cation and anion exchangers. However, selectivity differences for the latex-based exchangers can be modified, but usually not reversed. The cross-linking in the PSDVB core can be changed, the particle size of the latex particles can be changed, and the number of charged sites on the core versus the number in the latex microparticles can be altered. Consequently, resolution of anions or cations in IC can be improved by modification of one or more of these properties. A different particle core material can also be used. For example, acrylate-based latex anion exchangers have been prepared and are commercially available. These are often preferred for the separation of anions of high anion-exchange selectivity, such as phosphate and sulfate, because their retention on this anion exchanger is much less. Because of these modifications several different latex anion and cation exchangers have been developed for the separation of specific kinds of mixtures and are commercially available from Dionex Corporation. Furthermore, because both aminated and sulfonated groups are present in the latex-based exchangers, these exchangers are capable of exhibiting both anion- and cation-exchange properties simultaneously even though one group is in excess over the other.[9]

Figure 2 Latex-based ion exchangers, (a) anion exchanger, (b) cation exchanger.

3.3 Silica-based Ion Exchangers

Introduction of the bonded stationary phase, where the stationary phase is chemically bonded to silica (also now to alumina and zirconia) to HPLC was a milestone event in the development of HPLC. While the major thrust in the initial studies with bonded phases focused on the development of reversed stationary phases and to a lesser extent normal stationary phases, research also emerged on the synthesis of bonded-phase ion exchangers. Those of interest in IC are low in exchange capacity and are usually prepared by silanization chemistry.

Typically, silica-based ion exchangers are prepared by silanization of the silica silanol (Si−OH) sites with chlorosilane reagents that contain the ionogenic group, or groups that will undergo additional reactions to introduce the ionogenic groups. Strong acid ($-SO_3^-H^+$) and strong base ($-NR_3^+X^-$) silica-based cation and anion exchangers are commercially available as are weak acid ($-CO_2H$) and base ($-NH_2$) ion exchangers. The commercially available silica-based bonded-phase ion exchangers typically have high surface areas ($>200\,m^2\,g^{-1}$), are physically strong, do not swell/contract as solvent or electrolyte is changed, and provide high column efficiencies. However, they have a limited pH range of about pH 2 to 9 because of reactivity of the silica and the bonded group towards acid and base. They are commercially available as packed columns of uniform spherical microparticles of 3, 5, or 10 μm. Exchange capacities can be varied in the synthesis and in general those that are

commercially available and used in IC are low in capacity although their capacity is greater than the typical IC polymer and latex-based ion exchangers.

A pellicular-type silica-based ion exchanger is formed by depositing the ion exchanger matrix as a thin layer onto the surface of an inert core particle which is spherical, microparticle, and uniform in size. The ionogenic group is then attached to the matrix. Strong acid and base and weak acid and base ion exchangers have been made this way and several are commercially available. Typical core materials are a glass bead or a nonporous silica bead while the matrix layer is typically PSDVB or another polymer that provides reaction centers for the bonding of the ionogenic groups. One important weak acid pellicular-type cation exchanger with a silica core is an exchanger that has a poly(butadiene–maleic acid) copolymer covering and weak acid carboxy ($-CO_2H$) ionogenic groups. This type of cation exchanger is particularly useful for the simultaneous separation of alkali metals and alkaline earths (see Figure 3) with short analysis times and with a single eluent. This kind of separation is not easily accomplished with $-SO_3^-H^+$ polymer or latex-based cation exchangers.

Figure 3 Separation of analyte cations on a butadiene–maleic acid polymer-based cation exchanger. An aqueous 5.0 mM tartaric acid mobile phase at 1.0 mL min^{-1} with 10 µL injection of a sample 1 ppm Li^+, 5 ppm Na^+, 5 ppm NH_4^+, 10 ppm K^+, 10 ppm Mg^{2+}, 10 ppm Ca^{2+}, 20 ppm Sr^{2+}, 20 ppm Ba^{2+}, and direct conductivity detection. 3.4 Other Exchangers Used in Ion Chromatography

Other stationary phases used in IC are chelating ion exchangers and certain inorganic oxides and salts. Most chelating exchangers will contain acidic or basic groups that can participate in ion exchange in addition to the chelating group. The major interaction, however, is coordination between the analyte, usually a cation analyte, and the coordination center of the chelating exchanger. Chelating exchangers can be highly selective and this property can be predicted from known stability constants for complex formation between the analyte cation and the ligand in solution. Chelating ion exchangers are used more often for isolating and concentrating trace levels of cations rather than for the resolution of complex mixtures of cations. The high selectivity and stability of complex formation favors the former while slow exchange kinetics is a major handicap to the latter application. Few chelating ion exchangers for IC are commercially available.

Inorganic oxides and salts can participate in cation and/or anion exchange because they also exhibit weak acid and base properties. The ion-exchange property and ion-exchange capacity are therefore pH dependent. The exchange behavior of oxides also depends on many other environmental factors including buffer and inert electrolyte components and concentration in the mobile phase, pretreatment, heat treatment, ageing, method of preparation, crystallinity, and surface area. Furthermore, few are available as uniform spherical microparticles that meet high column-efficiency requirements. Notable exceptions are alumina, silica, and zirconia. Their uniqueness in IC applications comes from the fact that inorganic analyte anion and cation ion-exchange selectivities, and consequently analyte elution order, on the oxides and salts are often different to those obtained with the $-SO_3^-H^+$ and $-NR_3^+X^-$ cation and anion exchangers, respectively. Unfortunately, the stability of the inorganic oxides and salts as exchangers in an aqueous environment is not the same as the stability and reproducibility offered by the polymeric and latex-based ion exchangers.

4 ION EXCHANGE SEPARATIONS

Ion exchange is the main separation strategy that is used to separate ionic analytes. The chromatographic system consists of a separation or analytical column packed with an anion exchanger to separate anions or a cation exchanger to separate cations. The mobile phase will contain an electrolyte that provides a competing ion (anion for anion exchange and cation for cation exchange) of suitable ion-exchange selectivity (see Table 1) and concentration. When the mixture of analyte ions is introduced and carried into the column by

the mobile phase, the analyte ions are electrostatically attracted to the ionogenic groups. They are subsequently released to the mobile phase by competitive electrostatic attraction between the competing ions provided by the mobile-phase electrolyte and the analyte ions. Separation occurs because the analytes migrate through the column at different rates because of differences in their ion-exchange selectivities. The separation is completed by detection of the analyte ions as they emerge from the column. Absorption, fluorescence, and electrochemical detection are common detection modes in HPLC, but these detection strategies have limitations in direct detection of the ion-exchange separation of simple inorganic and organic anions and cations because most of these analytes are detector inactive. Conductivity, however, should be a universal detector for ionic analytes as most would have high ionic equivalent conductances. Unfortunately, conductivity detection in ordinary ion-exchange separations is not very sensitive because the analyte ion conductivity signal-to-noise ratio (S/N) is very small. In a typical ion-exchange separation the mobile phase itself is highly conducting because of the electrolyte required in the mobile phase.

Consider the case where an analyte mixture of Cl^-, Br^-, and I^- are being separated on an anion-exchange separator column capable of delivering high column efficiency. An aqueous NaOH mobile phase of suitable concentration is used and detection is by conductivity. The chromatographic set-up is shown in Figure 4. The sample is introduced as a small aqueous aliquot of sodium salts and the NaOH mobile phase carries the sample into the anion-exchange column. Anion exchange occurs according to the exchange equilibrium listed in Equation (5)

$$\mathbf{S}\text{–}NR_3^+OH^- + X^- = \mathbf{S}\text{–}NR_3^+X^- + OH^- \qquad (5)$$

where **S** is the exchanger matrix and X^- is Cl^-, Br^-, and I^-. Because of the anion ion-exchange selectivities (see Table 1) and the electrostatic competition between OH^- and the analyte anions towards the anion-exchange site, Cl^- travels the fastest and I^- the slowest and resolution starts to occur in the column as shown in Figure 4. When the analytes as the Na^+ salts emerge from the column as separated chromatographic zones they do so in the presence of the NaOH mobile phase. They subsequently pass into the conductivity detector where conductance of the flowing stream is determined. Because the conductivity for the NaOH is very high, the conductance signal caused by the presence of the three analytes is very small, S/N for the analyte anions is not favorable, and detection is poor. This is illustrated in the chromatogram in Figure 4, where the peaks correspond to the Na^+ salts of the analyte anions. If the NaOH was absent in the background, conductivity for the background would be very low and the three analyte signals would be very high. Thus, S/N would be very favorable and detection would be very sensitive. This major problem was solved by the suppressed IC strategy developed by Small et al.[1]

Figure 4 Separation of halides on an anion exchanger without postcolumn suppression.

5 SUPPRESSED ION CHROMATOGRAPHY

5.1 Suppression by an Ion Exchanger

In the suppressed IC strategy developed by Small et al.[1] a mixture of analyte anions or cations are separated by high-performance ion exchange and the analytes are detected by conductivity. In their strategy the key to a favorable S/N and sensitive detection is the removal or reduction of the mobile-phase background conductance due to the mobile-phase electrolyte. To separate analyte anions a low-capacity strong base anion-exchange column (separator or analytical column) is used for the separation and a high-capacity strong acid cation-exchange column connected in series serves as the suppressor column. For the separation of analyte cations the system is reversed or the analytical column is a strong acid low-capacity cation exchanger and the suppressor column is a high-capacity strong base anion exchanger. The basic instrumental set-up for anion and cation suppressed IC is shown in Figure 5(a) and (b), respectively.

Consider the nonsuppressed Cl^-, Br^-, and I^- anion-exchange separation illustrated in Figure 4. When this separation is carried out by an IC suppression strategy the effluent from the separator column is passed first

Figure 5 Separation of anions (a) and cations (b) with post-column suppression. P stands for a polymeric matrix of the exchanger.

into the suppression column of a strong acid cation exchanger charged in the H^+ form as shown in Figure 5(a) and then through the conductivity detector. In the suppression column NaOH, NaCl, NaBr, and NaI are converted to HOH, HCl, HBr, and HI, respectively, according to the exchange equilibrium summarized by Equation (6).

$$\mathbf{S}\text{–}SO_3^-H^+ + Na^+ = \mathbf{S}\text{–}SO_3^-Na^+ + H^+ \qquad (6)$$

Thus, when the effluent from the suppressor column passes through the conductivity detector the background is water and the analytes are the corresponding acids. Conductivity detection is therefore very sensitive because of the absence of the background conductance, S/N is high, and DLs are significantly reduced compared to the absence of the suppression column. The conductivity signals are also enhanced because the analytes are present as the acids rather than the Na^+ salts in the detection step. The ionic equivalent conductance for H^+ is about 7 times that of Na^+ which enhances the conductivity signal. This internal signal amplification is another advantage of the suppression system.

For the separation of analyte cations, for example the separation of Li^+, Na^+, and K^+ as Cl^- salts (see Figure 5b), a strong acid, low-capacity cation exchanger is used for the separator column and a strong base, high-capacity anion exchanger in the OH^- form is used for the suppressor column. An HCl mobile phase is used for the separation of the cation analytes. The separation occurs because of the differences in cation selectivities for the three analyte cations (see Table 1) and competition between the cations and H^+ for the cation-exchange sites. The exchange equilibria are summarized by Equation (7)

$$\mathbf{S}\text{–}SO_3^-H^+ + M^+ = \mathbf{S}\text{–}SO_3^-M^+ + H^+ \qquad (7)$$

where M^+ is Li^+, Na^+, and K^+. If the effluent from the separator column is passed directly into the conductivity detector in Figure 5(b), the detector would detect LiCl, NaCl, and KCl in that order on an HCl background. Conductance of the background is very high and conductance change due to the analytes would be small. However, if the effluent is passed into the suppression ion-exchange column, which is a high-capacity strong base anion exchanger charged in the OH^- form, the HCl background electrolyte and the alkali metal chloride analytes are converted to HOH and LiOH, NaOH, and KOH, respectively, as summarized by Equation (8)

$$\mathbf{S}\text{–}NR_3^+OH^- + Cl^- = \mathbf{S}\text{–}NR_3^+Cl^- + OH^- \qquad (8)$$

Thus, detection of each analyte by the conductivity detector is very sensitive because detection of the analyte takes place in an electrolyte-free background. Furthermore, the signal is enhanced because the analytes are detected as the OH^-, which has a much higher ionic equivalent conductance compared to Cl^-.

This separation/detection strategy was quickly recognized as a superior method for the rapid, accurate, and sensitive separation and determination of simple inorganic and organic ionic analytes. Analysis times and DLs obtained by this strategy were not possible by other methods.

The mobile-phase electrolytes used in Figure 5(a) and (b) are strong acid and base electrolytes, respectively, and when suppression is employed background conductance due to the electrolyte is overcome. Both eluents are modestly weak in eluent strength, which can be increased only by an increase in the concentration electrolyte. If a stronger eluent is required, which would be needed for example to separate highly retained analyte anions, an electrolyte that provides an anion of higher selectivity must be used (see Table 1). This is possible with suppression IC by using salts of weak acids and bases for the mobile-phase electrolyte in anion and cation separations, respectively. In the suppression step these electrolytes are converted to weak acids and bases, respectively. Because the weak acids and bases are poorly dissociated (K_a and K_b are therefore an important variable) their contribution to background conductance is low, S/N is favorable, and conductivity detection is still sensitive.

The suppression strategy outlined in Figure 5(a) and (b) had several limitations. DLs, while being favorable, were still limited by the analyte peak broadening that occurs in the separator column and even more so in the suppression column. Reduction of the broadening and an increased resolution was subsequently addressed by the development of new ion exchangers specifically designed for the separator column for IC and new, more versatile mobile-phase/electrolyte mixtures to separate the analyte anions and cations. A second recognized problem was that the suppression column's exchange capacity is exhausted in long-term operation, even though it has a high capacity. Therefore, continuous operation of this suppression IC system is not possible. The IC system would have to be shutdown either to replace or to regenerate the suppression column.

5.2 Membrane Suppression in Ion Chromatography

Development of a membrane suppressor[2,8] was subsequently shown to overcome these two major problems of the high-capacity ion-exchange suppressor column, namely, peak broadening in the suppressor and inability to carry out continuous IC owing to the required suppressor regeneration. A schematic representation of an anion membrane suppressor that would be used to suppress background electrolyte in the separation of anions is shown in Figure 6(a). The central region where the eluent flows is microvolume in size and is sandwiched by two sulfonated cation-exchange membranes. A regeneration chamber is on opposite sides of the membranes and the entire device is encased in a small leakproof unit.

Consider the IC separation shown in Figure 5(a) except that the ion-exchange suppression column is replaced by an anion membrane suppressor. As the column effluent from the anion-exchange separator column passes through the microvolume eluent chamber of the membrane suppressor, Na^+ is replaced by H^+ at the membrane. Simultaneously, a H_2SO_4 solution is continuously passed through the regeneration chamber and the Na^+ is then replaced by H^+. Thus, the suppression is continuous, band broadening is minimal, and conductivity DLs are significantly lower compared with those of the ion-exchange column suppression which was used in Figure 5(a). A 1–10 ppm DL (lower is possible) is often routine depending on the injection volume, analyte anion, and the separation conditions.

A cation membrane suppressor is also available and its schematic representation is shown in Figure 6(b). It functions much like the anion membrane suppressor except that the membrane is a strong base cation-exchange membrane charged in the OH^- form and the regeneration solution is usually an aqueous $R_4N^+OH^-$ solution.

The membrane suppressor has low internal volume and can be used continuously to reduce background conductance to almost negligible levels depending on the mobile-phase electrolyte and its concentration. It is efficient, rapid, reproducible, solvent resistant, and is compatible with gradient elution. Maintenance is low and only occasional cleaning is needed. The membrane suppressor is also readily adapted for on-line operation for automated IC in industrial applications.

The commercially available membrane suppressor has also undergone stages of improvement. The key improvements are the following. First the internal volume of the suppressor is now markedly reduced without sacrificing suppression properties and is currently referred to as a micromembrane suppressor (MMS). The MMS provides better DLs, better mass transfer across the membrane, and is better suited to smaller diameter analytical ion-exchange columns. A second key advance is the replacement of the suppressor membrane regeneration process by a continuous electrolytic regeneration process.[2,10] This modification is illustrated in Figure 7. In this case electrolysis of water is used to generate H^+ at the anode which is used to regenerate the anion MMS continuously, while for the cation MMS, OH^- produced at the cathode is used for the regeneration. The extra pump, the delivery system, and the H_2SO_4 solution are no longer required. Regeneration is simplified, continuous, more efficient (which also allows reduction in the internal volume of the suppressor), and is applicable to a wide range of mobile-phase electrolytes in both isocratic and gradient modes.

5.3 Other Suppression Strategies in Ion Chromatography

Other kinds of postcolumn suppression strategies have been described in the literature. However, none of these offer the sensitivity, simplicity, versatility in applications, and excellent reproducibility offered by a MMS. Nonmembrane suppression procedures include precipitation of the mobile-phase electrolyte but not the analyte in a suppressor ion-exchange column[11] or chelation[12] of the electrolyte in the suppression step. Another suppression procedure is to pump a slurry of small ion-exchange particles into the analytical column effluent following the separation and prior to conductivity

detection.[13] For example, if anions are being separated the separator column is an anion exchanger and colloidal (about 7 μm) strong acid cation-exchange particles in the H^+ form are continuously combined with the column effluent. Reactions describing the separation and the conversion of the analyte and the mobile-phase electrolyte to the H^+ form in the suppression step are the same (see Equations 5 and 6). Thus, the mobile-phase stream is converted into a low-conducting background while enhancing the analyte anion signal. The presence of the colloidal ion exchanger does not interfere in the conductivity detection.

Postcolumn suppression by an ion-exchange column can also be done effectively and efficiently. This configuration differs from the earlier ion-exchange suppressor unit described by Small et al.[1] in the following way. This system,[14] which is commercially available from Alltech Associates, Inc., includes two ion-exchange columns as the suppressor with either one of the two in operation at any given time. If anions are being separated the separator column is still an anion exchanger and the two suppression columns are strong acid cation-exchanger columns of high exchange capacity, small in size (14 mm × 7.5 mm), and low in internal volume. For cation-exchange separations the separator column is a cation exchanger and the two suppression columns are anion exchangers. The reactions describing the anion and cation separations and suppression are the same as described earlier. The system is continuous because when one suppressor column is being used the other is being regenerated and equilibrated simultaneously. When the first suppression column is exhausted, which is indicated by a color change of an indicator incorporated into the exchanger, a valve switches the separator column effluent to the second suppressor column and the first is regenerated and equilibrated while the second is used for suppression. The regeneration in this two-column suppressor strategy is also done by continuous electrolysis of water. Continuous separations are therefore possible. Also, the suppressor need not be large so that band broadening and reduction in S/N are avoided and DLs are low.

MMSs have applications other than mobile-phase electrolyte suppression in IC. For example, the suppressor can be applied to sample cleanup prior to IC analysis.[15] Another practical application is to use the suppressor to remove NaOH (up to 48%) from a concentrated NaOH solution prior to trace IC anion analysis in the NaOH solution.[16] The MMS can also be used to enhance detection of organic analytes that are separated on reversed-stationary-phase columns when employing a mobile phase of high ionic strength. When these analytes cannot be detected by absorbance or fluorescence, the mobile-phase ionic strength electrolyte can be converted to a weakly conducting species with the MMS. Thus, the analytes can then be detected by conductivity with good sensitivity. For example, anionic surfactants are separated on reversed stationary phases with good resolution only if the mobile phase is at a high ionic strength. The mobile-phase ionic strength electrolyte, which is a salt of a weak acid, is suppressed by an MMS which allows a sensitive conductometric detection of the anionic surfactant.[17]

6 ELUENTS FOR SUPPRESSED ION CHROMATOGRAPHY

Eluent strength is determined by the mobile-phase electrolyte concentration and the electrolyte anion for the IC separation of anions and electrolyte cation for the IC separation of cations. A higher concentration or an ion of higher ion-exchange selectivity yields a stronger eluent.

Table 3 lists several common electrolytes that are used in the suppressed IC separation of anions. Eluent strength, in general, will increase from top to bottom although differences may be small depending on the electrolyte mobile-phase concentration. The key factors to optimize are: the mobile-phase electrolyte anion, the electrolyte concentration, and selection of the anion exchanger. If an electrolyte containing a weak acid anion is used, S/N, and hence DL, will depend on dissociation of the weak acid that is formed in the suppression step.

The useful electrolyte cations for suppressed analyte cation IC separations are few in number. If the suppression step involves OH^-, hydroxide precipitation depending on the electrolyte cation can interfere in suppressor and conductivity-detector performance. Many cation analytes, particularly multivalent cations, have high, similar cation-exchange selectivities and require a strong eluting condition. Because of the similarity in selectivities resolution is often poor even with a strong eluent electrolyte. This problem can be overcome in some cases by using a carboxylate-type cation exchanger or

Table 3 Common electrolytes used in mobile phases in suppressed IC

Separation of anions	Separation of cations
$Na_2B_4O_7$	HCl

Tyrosine	

DAP, 2,3-Diaminopropionic acid.

more often by including a complexing agent in the mobile phase. Thus, formation constants for the complexes that form between the complexing agent and the multivalent cations will determine the cation elution order. Typical complexing agents used in the mobile phase in addition to an electrolyte are ethylenediaminetetraacetic acid (EDTA) and citrate, tartrate, 2-hydroxybutyrate, and pyridine-2,6-dicarboxylate salts.

Alkali metal, other univalent and alkaline earth cations can be separated with suppression using strong mineral acids, alkyl sulfonic acids, and protonated forms of organic bases such as aniline, ethylenediamine, phenylenediamine, and DAP as the mobile-phase electrolyte. The eluent strength of the latter three are also pH dependent since they are polyprotic acids.

The electrolysis of water, which is the basis for electrochemical regeneration of the MMS, offers other advantages in IC separations. This strategy can be used in IC separations not only to prepare a highly purified mobile phase but also to increase electrolyte concentration electrically in the mobile phase for a gradient application. For example, a carbonate-free NaOH mobile phase can be prepared via water electrolysis and used for IC anion separation.[18,19] Removal of the carbonate significantly lowers the DL for the separated anions.

A new version of IC, called *ion reflux*, also employs water electrolysis in a unique way to generate the mobile phase.[19,20] Analytes are still separated by ion exchange and an electrolyte solution is still the eluent, but it is pure water that is pumped into the system. In ion reflux the electrolyte solution is generated in situ via electrolysis and either analyte anions or cations can be separated.

Figure 8 illustrates an ion-reflux unit for the IC separation of analyte anions. The unit is composed of a source of pure water, a pump, a sample injector, an anion-exchange separator column where the separation of the analyte anions takes place after the sample is injected into the ion-reflux unit, and a generator system where the eluent is formed. This generator system contains two cation exchangers, one is charged in the K^+ form and is placed at the top while the bottom one is charged in the H^+ form as shown in Figure 8. The cathode is in a cathode chamber and is separated from the K^+ cation exchanger by a cation-exchange membrane (shown as the black region in Figure 8). Cations will pass through the membrane but anions do not owing to Donnan exclusion. When the potential is applied and pure water is flowing through the unit, electrolysis of the water will occur at the electrodes with OH^- as KOH (now the eluent electrolyte) forming at the cathode and H^+ at the anode. The H^+ produced at the anode helps to move the K^+ through the cation-exchange membrane to form the KOH eluent. However, a steady state occurs in the generator because the eluent KOH and the separated

Figure 8 Schematic representation of an ion-reflux unit for the IC separation of analyte anions. Only key components are shown and not drawn to scale. (Reproduced by permission of American Chemical Society, from H. Small, J. Riviello, *Anal. Chem.*, **70**, 2205, (1998).[20])

analyte anions, after passing through the anion separator column, eventually reach the K^+/H^+ cation-exchanger boundary of the generator part of the unit. At this point the KOH comes into contact with the H^+-form cation exchanger and is converted to HOH and the K^+-form cation exchanger. Thus, this is both the suppression step and a recharging of the K^+ cation exchanger. In addition the analyte anions are converted into the acids which eventually pass through the conductivity detector. Since OH^- and H^+ are produced in equivalent amounts during the electrolysis, the K^+/H^+ boundary remains fixed when the steady state is established since K^+ or H^+ are not lost in the operation assuming the sample anions are introduced as the acids. Thus, ion reflux is water in and water plus the separated analyte anions out.

The elution process can be either isocratic or gradient, even though pure water is pumped into the unit. When the current is held constant, a fixed known eluent concentration is generated and the elution is isocratic. If the current is gradually increased in a

known, reproducible manner, then a known, reproducible concentration gradient in OH^- as KOH is produced.

For the separation of cations in an ion-reflux unit the separating column is a cation exchanger and the other two exchangers in the generator part of the ion reflux unit are anion exchangers. The top anion exchanger is charged in either the Cl^- or $CH_3SO_3^-$ form and is separated from the electrode by an anion-exchange membrane while the exchanger at the bottom is charged in the OH^- form.[20]

7 NONSUPPRESSED ION CHROMATOGRAPHY

In nonsuppressed IC, analyte anions are separated usually on a strong base-type anion exchanger, and analyte cations on a strong acid-type cation exchanger. A typical IC set-up for nonsuppressed separation of anions, for example, is similar to that shown in Figure 4. If conductivity detection is used no attempt is made to reduce background conductivity by removal of the background electrolyte. The influence of background conductance on S/N and therefore DL is overcome by altering other factors in the ion-exchange process.

Fritz et al.[21,22] exploited two features of ion exchange to improve conductivity detection in the absence of suppression. First, an ion exchanger was used that is very low in ion-exchange capacity but still capable of providing a high efficiency separation. Typically, this is in the range of $7-100\,\mu eq\,g^{-1}$. Thus, mobile-phase electrolyte concentration required for the separation will be very low and therefore mobile-phase background conductance will be very low. The second modification is to use a mobile-phase electrolyte that provides an eluent anion (for analyte anion separations) or cation (for analyte cation separations) with a high ion-exchange selectivity and an ionic equivalent conductance that differs significantly from the analyte ions. When these two adjustments in the methodology are made and a quality conductivity detector is used that has excellent conductivity offset capabilities and good temperature control, conductivity change due to the analyte gives a good S/N and therefore a favorable DL. Improvements in conductivity-detector electronic suppression of conductivity background and temperature control also contribute to the increased capabilities of nonsuppressed IC.

When the ion-exchange column exchange capacity and the mobile phase electrolyte and its concentration are optimized and a quality conductance detector with good electronic offset, temperature control, and low internal cell volume is used, DLs by nonsuppressed IC often approach those obtained by suppressed IC. Since the exchange capacity is very low, care is needed to avoid column overload with the sample. A major advantage offered by nonsuppressed IC is that this approach is compatible with other types of detection in addition to conductivity. This broadens the scope of applications and sensitivity of nonsuppressed IC. Both direct and indirect absorption, fluorescence, and electrochemical detection methodologies can be used where applicable. In addition nonsuppressed IC is compatible with postcolumn reactions to convert the analytes into products that absorb, fluoresce, or are electrochemically active.

8 ELUENTS FOR NONSUPPRESSED ION CHROMATOGRAPHY

Table 4 lists several common electrolytes employed as mobile-phase electrolytes for the separation of anions. These represent a wide range of eluent strength but are not listed in order of eluent strength. Several have low limiting ionic equivalent conductances, particularly the salts of organic acids, and dilute solutions of these are compatible with conductivity detection. Others are more compatible with other detection strategies. Those that are multiprotic can be changed in eluent strength not only by concentration but also by pH which will determine the charge of the mobile-phase anion.

Borate salts and EDTA are mobile-phase electrolytes whose eluent strength can be varied over a wide range. Borate forms complexes with neutral and acidic polyhydroxy compounds such as sugars and tartaric or gluconic acid, respectively. The charge of the complex, which will determine the eluent strength, depends on the borate concentration, the polyhydroxy compound and its concentration, their ratio, and the pH. At a higher pH a mononegative 1:1 complex forms, which is a weak

Table 4 Common eluent electrolytes for nonsuppressed ion chromatographic separation of anions

Monoprotic acids	Multiprotic acids
Formic acid	HCO_3^-/CO_3^{2-}
Acetic acid	Borate/hydroxy compounds
Benzoic acid and derivatives	*o*-Phthalic acid
Benzenesulfonic acid and derivatives	Tartaric acid
Naphthylamine sulfonic acid and derivatives	Fumaric acid
Alkane sulfonic acids	1,3,5-Tricarboxybenzene
Mineral acids	EDTA
	Sulfobenzoic acid
	Sulfophthalic acid

eluent, low in conductivity, and therefore suitable for conductivity detection. EDTA is a tetraprotic acid and will be present in the mobile phase as a -1 to -4 anion depending on the pH. It is a strong eluent anion as a multivalent anion and is suitable for the elution of highly retained anions, such as polyphosphate analyte anions.

While a strong base, such as a NaOH or KOH mobile phase is easily used in analyte anion separations by suppressed IC, these strong base mobile phases are not suitable for nonsuppressed IC with conductivity detection because the OH^- has such a high ionic equivalent conductance. A salt of a weak acid is a much better mobile-phase electrolyte. A mobile phase containing a strong base, however, is preferred when separating anions of low anion-exchange selectivity or anions derived from very weak acids, such as HCN or H_3BO_3, because OH^- provides a mobile phase of low eluent strength. If a strong base is used, typically a detection method other than conductivity is used.

Electrolytes for the nonsuppressed IC separation of analyte cations are fewer in number compared to nonsuppressed anion IC. A strong mineral acid mobile phase, such as HCl or HNO_3, can be used but is incompatible with conductivity detection, if low DLs are required, because of high ionic equivalent conductance caused by H^+. Buffered solutions of organic bases, such as benzylamine, pyridine, aniline, pyridinecarboxylic acid, and isonicotinic acid are used to obtain the protonated base as the mobile phase electrolyte cation. Ethylenediamine with tartaric acid or α-hydroxybutyric acid, oxalic acid/citric acid mixtures, and pyridine-2,6-dicarboxylic acid eluents are also used and provide both a strong eluent cation and complexing conditions. If multiprotic bases are used, such as ethylenediamine, phenylenediamine, DAP, or polyamines, than multivalent mobile-phase cations are obtained that are much higher in eluent strength depending on mobile-phase pH and pK_b values for the base. Quaternary ammonium (R_4N^+) salts, which can be strong mobile-phase cations depending on the structure of R, can be used but these also can undergo interaction with the cation exchanger matrix particularly if it is a PSDVB polymeric-based cation exchanger. Mono and divalent inorganic cations provide a wide range of eluent strength. However, they are not usually employed with conductivity detection but are applicable to other detection modes. For example, Cu^{2+} or Ce^{3+} are both strong eluent cations ($Ce^{3+} > Cu^{2+}$) and are good mobile-phase electrolytes for the separation and resolution in the nonsuppressed separation of mono and divalent cations on a cation exchanger. Both Cu^{2+} and Ce^{3+} absorb, and thus, detection by indirect absorbance detection is possible. The Ce^{3+} also fluoresces and sensitivity is better with Ce^{3+}, if an indirect fluorescence detection mode is employed.

9 DETECTION IN ION CHROMATOGRAPHY

Most detection strategies used in LC are applicable to IC separations.[1–5,7] However, conductivity detection is the detection method of choice in virtually all suppressed IC separations since the suppression strategy overcomes the limiting effects of a mobile-phase conducting background (see Figure 5a and b). The conductance cell contains microelectrodes; consequently, cell volume is very small often corresponding to a few nanoliters and cell contribution to band broadening is small. Response is rapid, reproducible, sensitive (about 5×10^{-9} g mL^{-1}), and has a linear dynamic range of over three orders of magnitude provided the conductivity cell temperature is constant. While conductivity detection is also widely applied in nonsuppressed IC, other detection strategies are equally as important.

Spectroscopic detection methodology is second to conductivity detection in IC separations and is frequently used with nonsuppressed IC separations. Many inorganic and organic analyte ions absorb in the UV (ultraviolet) or visible region and a direct detection of absorbance change due to change in analyte ion concentration is straightforward. Fluorescence on the other hand is more selective since fewer analyte ions, particularly inorganic analyte ions, will fluoresce. DLs are specific to the analyte ion and will depend on its molar absorptivity for the former detection mode and the fluorescence yield in the latter.

Both absorption and fluorescence detection can be used in a direct or indirect mode. In the direct detection mode, absorbance or fluorescence of the analyte ion is determined in the presence of little or no absorbance or fluorescence in the background. As analyte ion concentration increases, its absorbance or fluorescence increases resulting in the analyte band appearing as a positive peak in the chromatogram. The peak height and peak area are proportional to analyte ion concentration and this correlation is the basis for calibration and subsequent determination of unknown samples of the same analyte ion. In the indirect detection mode the mobile-phase electrolyte absorbs or fluoresces and the analyte ion does not. Since the analyte ion competes with the electrolyte ion of the same charge for the ion-exchange site, a decrease in absorbance or fluorescence, which is due to this exchange competition, is observed on an absorbing or fluorescent background. Thus, negative detection peaks for the separated analyte ions are obtained in the chromatogram whose peak heights and

areas are proportional to each analyte ion concentration. If analyte anions are being separated, the mobile-phase electrolyte must provide an absorbing or fluorescing anion, while for cation separations the electrolyte cation must absorb or fluoresce. Indirect detection strategies are also feasible when using ion interaction reagents as illustrated later. The essential criteria that must be met for calibration, and the handling of the data in these direct and indirect detection strategies in quantitative determination applications is reviewed elsewhere.[2]

Atomic spectroscopic detection strategies are useful in IC separations but limited to those kinds of analyte ions that can be atomized into the vapor state following the separation. Thus, both atomic emission and absorption methodologies are selective rather than universal detection strategies. These modes of detection have been shown to be both sensitive and reliable, where applicable, in IC separations. Of particular interest is detection by inductively coupled plasma mass spectrometry (ICPMS) since both qualitative identification and quantitative determination is possible with this detection system.

Another detection strategy that is vital in IC separations, particularly in the detection of inorganic ions, is a postcolumn reaction that produces a species that absorbs, fluoresces, or is photoluminescent. In this strategy the column effluent containing the separated analyte ions is combined with reagents postcolumn in a controlled way and the conditions are adjusted to produce the detector-active species. For inorganic analyte cations the reaction is often one that involves a formation of a detector-active complex. A successful postcolumn reaction must be reproducible and therefore careful control of the reaction conditions is vital. Typically, reaction time, temperature, pH, mixing rate, and reagent concentrations are parameters that must be optimized according to the chemical reaction and these details are discussed elsewhere.[1–5] Table 5 lists several postcolumn reagents that are routinely used for postcolumn detection in the IC separation of inorganic analyte anions and cations. Since detection is determined by the chemical reaction, selectivity can be incorporated into the detection step by using a reagent for the postcolumn reaction that is selective in its chemistry.

10 APPLICATIONS OF ION CHROMATOGRAPHY

IC is an indispensable analytical technique for the determination of common inorganic and organic analyte ions. As indicated in Figure 1 the method is rapid, reproducible, has excellent DLs and is applicable to trace quantities, can be insensitive to sample matrices, is applicable to complex mixtures, and is accurate and precise. For anion analysis IC is the method of choice for both simple and complex mixtures and has for the most part replaced chemical and other instrumental methods for anion analysis. For cation analysis IC is a companion method to emission and absorption spectroscopic methodologies, but IC does have the advantage of being more applicable to simultaneous multication analysis.

IC is vital to water analysis and frequently is the basis for officially approved methods. It is a routine method in studying drinkable water and rain water. Any industry, such as environmental, clinical, agricultural, pulp and paper, mining, chemical, pharmaceutical, power plant, electronic, and others, that depends on water quality will utilize IC in its analytical laboratories. Numerous examples are in the literature demonstrating the importance of IC in water quality studies. For example, Figure 9(a) and (b) illustrate anion analysis of drinking water and rain water, respectively, where the separation is complete in minutes, while Figure 9(c) shows the separation of the transition metals in an industrial wastewater sample. Suppressed conductivity is used in Figure 9(a) and (b). In Figure 9(c) the transition metals are detected via a postcolumn reaction. Following the separation on the cation exchanger the metal ions are

Table 5 Selected postcolumn reactions used for detection in IC

Analyte	Postcolumn reagent	Reaction	Detection
Inorganic anions	$Fe(ClO_4)_3$	Fe^{3+}-anion complexes	Absorption, 300–340 nm
Phosphorus oxy anions	Mo^{5+}/Mo^{4+}	Phosphomolybdate	Absorption, 830 nm
Phosphorus oxy anions	Al^{3+}-morin	Al^{3+}-anion complexes	Fluorescence, 480 nm
Transition and heavy metals	PAR	Complexes	Absorption, 490–530 nm
Lanthanides, alkaline earth metals	Arsenazo III	Complexes	Absorption, 570 nm
Transition metals	Dithizone	Complexes	Absorption, 590 nm
Zr^{4+}, rare earths, Sc^{3+}, Al^{3+}, Zn^{2+}, Cd^{2+}, Ca^{2+}, Mg^{2+}	8-Oxine	Complexes	Fluorescence, 530 nm
Al^{3+}	Tiron	Complex	Absorption, 310 nm

PAR = 4-(2-pyridylazo)-resorcinol, morin = 2′,3,4′,5,7-pentahydroxyflavone, arsenazo III = 2,7-bis(2-arsonophenylazo)-1,8-dihydroxynaphthalene-3,6-disulfonic acid, dithizone = diphenylthiocarbazone, 8-oxine = 8-hydroxyquinoline, tiron = 4,5-dihydroxy-1,3-benzenedisulfonic acid.

Figure 9 IC anion analysis of (a) drinking water and (b) rain water and cation analysis of (c) industrial wastewater. (a) An aqueous 0.15 mM $NaHCO_3$, 2.0 mM Na_2CO_3 mobile phase at 2.0 mL min^{-1} with 25 µL injection on a Fast-Sep anion-exchange column and suppressed conductivity detection. (b) An aqueous 2.8 mM $NaHCO_3$, 2.2 mM Na_2CO_3 mobile phase at 2.0 mL min^{-1} with 50 µL injection on a IonPac AS4 anion-exchange column and suppressed conductivity detection. (c) An aqueous 50 mM $H_2C_2O_4$, 95 mM LiOH mobile phase at 1.0 mL min^{-1} with 50 µL injection on a IonPac CS5 cation-exchange column with detection at 520 nm after a postcolumn reaction with PAR. (Reproduced by permission of Wiley-VCH from J. Weiss, *Ion Chromatography*, 349, 352, and 357.[2])

combined with PAR and the metal-ion–PAR complexes are detected by absorption at 520 nm.

The excellent resolving power of IC is demonstrated in Figure 10 where 36 analyte anions are separated in about 30 min. Figure 10 also shows that IC is applicable: (1) to the separation of the more highly retained multivalent anions, (2) to organic anions such as the simple carboxylic acids which are important in the food and health sciences, and (3) that gradient elution is readily carried out with suppressed IC using conductivity detection. Although not discussed here gradient elution is also a viable elution strategy with nonsuppressed IC.[2–5]

IC is applicable to ultratrace analysis as shown in Figure 11(a) and (b). Often in these trace-analysis applications concentration of the analyte is required and the IC instrumentation is modified to include this operation. An example of IC trace analysis is illustrated in Figure 11(a), where the IC chromatogram for the determination of SO_4^{2-} in pure NaCl is shown. The Cl^- is removed by a precolumn and the SO_4^{2-} is detected after separation on an anion exchanger by suppressed conductivity. If required, Br^- and NO_3^- can also be determined but absorption detection would be more sensitive. Figure 11(b) illustrates the IC chromatogram for the determination of transition metals in 50% NaOH. The trace metals are concentrated on a precolumn, then separated by cation exchange, and subsequently detected postcolumn by absorption after reaction with PAR.

11 ION EXCLUSION CHROMATOGRAPHY

IEC is an ion-exchange method which allows the separation of ionic analytes from nonionic analytes and

Figure 10 IC separation of a complex mixture of inorganic and organic anions with a gradient elution and suppressed conductivity detection. An aqueous mobile phase of 0.75 mM NaOH for 5 min and gradient to 85 mM NaOH in 30 min at 1.0 mL min^{-1} with a sample that was 10 ppm in each analyte except where noted, containing (1) F^- (1.5 ppm), (2) α-hydroxybutyrate, (3) $C_2H_3O_2^-$, (4) glycolate, (5) butyrate, (6) gluconate, (7) α-hydroxyvalerate, (8) formate (5 ppm), (9) valerate, (10) pyruvate, (11) monochloroacetate, (12) BrO_3^-, (13) Cl^- (3 ppm), (14) galacturonate, (15) NO_2^- (5 ppm), (16) glucoronate, (17) dichloroacetate, (18) trifluoroacetate, (19) phosphite, (20) selenite, (21) Br^-, (22) NO_3^-, (23) SO_4^{2-}, (24) $C_2O_4^{2-}$, (25) selenate, (26) α-ketoglutarate, (27) fumarate, (28) phthalate, (29) oxalacetate, (30) PO_4^{3-}, (31) AsO_5^{3-}, (32) CrO_4^{2-}, (33) citrate, (34) isocitrate, (35) *cis*-aconitate, (36) *trans*-aconitate on a Dionex AS5A anion-exchange column with suppressed conductivity detection. is most often employed in the separation of mixtures of weak acids or bases. Ordinary high-capacity ion exchangers, usually the PSDVB type exchangers, are used. Weak acid analytes are separated on strong acid ion exchangers and weak bases are separated on strong base ion exchangers. Instrumentation for HPLC is used in IEC and detection is often by conductivity with or without suppression or by absorbance if the analytes are chromophoric.

While ion exchangers are used as the stationary phase in IEC, an exchange of ions is not responsible for the separation as the analytes travel through the column in the mobile phase.[2–4] Consider the case where the weak acid acetic acid is the analyte, the mobile phase is an aqueous HCl solution, and the stationary phase is a PSDVB-$SO_3^-H^+$ cation exchanger. A simplified schematic illustrating what happens in the column is shown in Figure 12. The system is composed of three main components: one is the solid PSDVB polymeric network, the second is the stationary phase represented by the hydrated $-SO_3^-H^+$ sites, and the third is the mobile phase traveling around and between the exchanger particles. A Donnan-like membrane is established through which certain species only are able to penetrate. Neutral molecules penetrate and ions similar in charge to the co-ions (H^+ in Figure 12) pass into the exchanger resin phase, but ions of similar charge to the ionogenic group, for example $C_2H_3O_2^-$ in Figure 12, do not. The amount of ionized and neutral undissociated forms of the analyte will depend on the analyte's dissociation constant. Strong acid (and base) analytes, which are completely dissociated, are electrostatically repulsed and travel with a volume of mobile phase that corresponds to the column void volume. Partially dissociated analytes, such as acetic acid in Figure 12,

Figure 12 Schematic description of ion exclusion.

penetrate into the resin phase and are therefore retarded in their movement through the column. Elution of the partially dissociated analytes will often correspond to their ionization constants; that is the least dissociated travels the slowest through the column.

While dissociation is a key factor which influences analyte movement through the column in IEC, other factors are also significant depending on the analyte and the ion exchanger used for the IEC separation. Other principal contributing factors influencing analyte retention and elution order are interaction of the analyte with the exchanger matrix (adsorption), analyte size (size exclusion), and polar interactions between the analyte and the exchanger ionogenic group. Because of these interactions, which can be significant, certain neutral molecules can also be retained and resolved on ion exchangers.

IEC is widely used for the separation of weak organic acids. The role of the mobile phase is to dissolve the sample and act as a carrier of the analytes through the column. Often water is the mobile phase. Since dissociation is a key factor in IEC, ionization of weak acid analytes can be suppressed to enhance retention and resolution by including a mineral acid, for example HCl or H_2SO_4, in the mobile phase. Also, acetonitrile or alcohols are added to the mobile phase to increase analyte solubility, influence dissociation, and/or to alter weak acid analyte–exchanger matrix interactions.

IEC is widely used to separate complex mixtures of weak organic acids. In addition IEC is a good method for separating carbohydrates, aldehydes, ketones, and alcohols as neutral molecules. Because of these kinds of application IEC is invaluable as a separation method in the food/beverage industry and in the health sciences.

Figure 13 IEC separation of organic acids in a human urine sample. A 1:9 MeOH:H_2O 10 mM H_2SO_4 mobile phase and an Interaction ORH 801 cation-exchange column with detection at 254 nm. Analytes are: (1) oxalic acid, (2) oxaloacetic acid, (3) α-ketoisovaleric acid, (4) ascorbic acid and α-keto-β-methyl-*n*-valeric acid, (5) β-phenylpyruvic acid, (6) uric acid, (7) α-ketobutyric acid, (8) homoprotocatechuic acid, (9) unknown, (10) unknown, (11) hydroxyphenylacetic acid, (12) *p*-hydroxyphenylacetic acid, and (13) homovanillic acid. Figure 13 illustrates an IEC separation on a commercially available high-capacity cation exchanger of organic acids that are present in a human urine sample.

12 ION INTERACTION CHROMATOGRAPHY

Charge on an organic analyte sharply reduces its retention on a reversed stationary phase often leading to low retention and poor resolution on the reversed stationary phase. The scope of reversed-phase HPLC can be broadened when a lipophilic ion with a charge opposite to the analyte ion charge is included in the mobile phase. Increased retention, selectivity, resolution, and even an increased number of detection options are often realized. This separation strategy to enhance retention and resolution is particularly important in the application

of reversed stationary phases to the separation of mixtures of biological molecules containing acidic or basic groups.

These advantages are also realized when a lipophilic ion opposite in charge is added to the mobile phase to increase retention and resolution in the separation and determination of inorganic and simple organic anions and cations on a reversed stationary phase. This strategy, which is often called IIC or ion pair chromatography, is a useful alternative separation methodology to IEC. To separate analyte anions, a lipophilic cation, such as a tetraalkylammonium salt (for example, $R_4N^+Cl^-$) is added to the mobile phase, while to separate analyte cations, a lipophilic anion, such as a long alkyl-chain sulfonic acid (for example $RSO_3^-H^+$), is added to the mobile phase. Several equilibrium steps contribute to the overall retention of the analyte ion, thus several column and mobile-phase parameters must be optimized and carefully controlled to obtain reproducible separation results. These include pH if analytes and the lipophilic ion are weak acids or bases, buffer components and concentration, ionic strength, selectivity of counterions, mobile-phase organic solvent/water ratio, type of organic solvent, hydrophobicity of the R group in the lipophilic ion, concentration of the lipophilic ion, and the type of reversed stationary phase used.[23,24]

Either silica reversed stationary phases or PSDVB reversed-phase adsorbents are suitable stationary phases. The former offers the major advantages of better mass transfer, better column efficiency, and a better and reproducible stationary-phase surface. The latter offers pH stability throughout the pH range, often higher analyte retention, and larger analyte loading capacity.[2,3,23,24]

Much research has gone into establishing a retention model that is consistent with all the experimental results. For a mobile phase that is largely aqueous and buffered, a lipophilic salt that readily dissociates and is well below its critical micelle concentration and modest in ionic strength, analyte-ion retention on the reversed stationary phase can be described by the ion interaction model. When the mobile phase containing an appropriate concentration of the lipophilic ion, buffer, and ionic strength electrolyte in a mixed organic modifier/water solvent are passed through the reversed stationary phase column, an equilibrium amount of the lipophilic ion and its counterion are maintained on the reversed stationary-phase surface as a double layer. A schematic illustration of the key elements of this model for the case where $R_4N^+C^-$ is the mobile phase lipophilic ion that is continuously passed through the column is shown in Figure 14. When analyte anions represented by X^- in Figure 14 enter the column they compete with C^- in the diffuse secondary layer for the R_4N^+ sites. Differential migration of the different analyte anions occurs because of the preference the R_4N^+ shows for one analyte anion over another compared to C^- just as if it were an anion-exchange selectivity. The similarity is such that the elution order for inorganic analyte anions follows the selectivity for strong base anion exchangers listed in Table 1.

Retention of analyte cations would be described by a similar model except that the lipophilic reagent would be anionic, for example $RSO_3^-H^+$. The primary layer on the reversed stationary phase is RSO_3^- and the countercation in the secondary diffuse layer is H^+ or some other countercation provided by the mobile-phase buffer or ionic strength electrolyte. The analyte cations are therefore in competition with these cations in the diffuse layer.

Suppression methods can be used with analyte anion and cation separations by IIC to enhance conductivity detection. The MMS used when separating anions must contain an organic solvent-resistant membrane that is permeable to the lipophilic cation, for example R_4N^+, while the MMS for cation IIC separations must contain an organic solvent-resistant membrane permeable to the lipophilic anion, for example, RSO_3^-. Both are available commercially. Conductivity detection can be used with nonsuppressed IIC but DLs are usually not as good as those obtained by suppressed IIC. Figure 15 illustrates the chromatogram for the separation of inorganic anions on a C_{18} reversed stationary phase with a quaternary ammonium salt as the mobile-phase lipophilic ion additive and nonsuppressed direct conductivity detection.

Direct absorbance or fluorescence detection is also a viable and widely used detection mode in nonsuppressed IIC when analytes absorb or fluoresce. Indirect absorption or fluorescence detection in IIC also provide good DLs when analyte ions do not absorb or fluoresce. In one approach the counterion, C^- or C^+ (see Figure 14), to the lipophilic ion that is used for analyte anion or cation separations, respectively, absorbs or fluoresces.[25] As the analyte anion or cation band

Figure 15 IIC of inorganic anions on a reversed stationary phase. A 2.0 mM tetrabutylammonium hydroxide, 50 mM phosphate pH = 6.7 buffered mobile phase at 2.0 mL min^{-1} with 20 µL injection on a Lichrosorb RP-18 reversed stationary phase column and direct conductivity detection. Each analyte is about 1000 ppm. (Reproduced from P.R. Haddad, P.E. Jackson, *Ion Chromatography Principles and Applications*, 170. Copyright (1990) with permission of Elsevier Science.[3])

Figure 16 IIC separation of (a) inorganic and (b) organic anions on a reversed stationary phase with indirect absorbance detection. (a) An aqueous 0.1 mM Fe(1,10-phenthroline)$_3SO_4$, 0.1 mM succinate, pH = 6.1 buffered mobile phase at 1.0 mL min^{-1} and a PRP-1 reversed stationary phase. Each analyte was about 1 µg and indirect absorbance detection was at 510 nm. (b) Same as (a) except 0.1 mM Fe(1,10-phenthroline)$_3$ $(ClO_4)_2$ 0.1 mM succinate, pH = 6.1 mobile phase. SP = system peak. (Reprinted by permission from P.G. Rigas, D.J. Pietrzyk, *Anal. Chem.*, **58**, 2226 (1986) and *Anal. Chem.*, **59**, 1388 (1987). Copyright American Chemical Society.[26,27])

moves down the column an equivalent amount of C^- or C^+ in the band is displaced by the analyte ion causing the absorbance or fluorescence in the band to be less relative to the background absorbance or fluorescence. Thus, the analyte peaks appear as negative chromatographic peaks. In a second approach the lipophilic ion itself absorbs or fluoresces.[26,27] Figure 16(a) and (b) show a separation of inorganic and organic anions, respectively, on a reversed stationary phase using the $[Fe(II)-(1,10\text{-phenanthroline})_3]^{2+}$ complex as the mobile phase lipophilic ion. As the analyte anions travel through the column an ionic strength difference in the analyte band relative to the background causes the amount of the complex to be greater in the analyte band. Thus, the analyte peaks appear as positive chromatographic peaks in the chromatogram.

ABBREVIATIONS AND ACRONYMS

DAP	2,3-Diaminopropionic Acid
DL	Detection Limit
EDTA	Ethylenediaminetetraacetic Acid

Micellar electrokinetic chromatography (MEKC) is a highly efficient miniaturized separation technique that is performed with the same experimental set-up that is used with capillary electrophoresis (CE). While the separation principle of CE is based on differences in the electrophoretic mobility of the solutes to be separated (only charged species can be separated), in MEKC separation is also based on differences in the distribution constants between two phases migrating at different velocity due to electrokinetic effects. The second phase is introduced into the separation electrolyte by adding an ionic surfactant (anionic or cationic) at a concentration above the critical micelle concentration (CMC). Aggregates of surfactant monomers (micelles) are present in the separation electrolyte. These aggregates have an electrophoretic mobility and are able to incorporate solutes or interact strongly with species dissolved in the surrounding medium.

MEKC extends the applicability of CE to neutral solutes. In addition, MEKC has been proven to be superior to CE in the separation of very complex mixtures of solutes with similar electrophoretic mobility, because of the various factors that are available for the manipulation of separation selectivity. Currently, MEKC can be regarded as a separation technique with a similar scope to that of reversed-phase high-performance liquid chromatography (RPHPLC), having advantages over the latter concerning the efficiency of the separation system, separation speed, cost and tolerance to matrix constituents, as in MEKC no stationary phase is present that can be fouled by irreversible sorption of matrix constituents of the sample. Owing to the small injection volume (a few nanoliters) and small detection volume that is necessary to avoid intolerable instrumental band broadening, current MEKC instrumentation restricts the applicability of MEKC to the determination of those compounds in complex mixtures that are present in concentrations sufficiently high with respect to the limits of detection that can be obtained with such instrumentation.

1 INTRODUCTION

MEKC as a miniaturized separation technique for both charged *and* noncharged species was initially developed by Terabe et al.[1,2] A theory of the separation principles involved is based mostly on investigations employing the anionic surfactant sodium dodecyl sulfate (SDS) as the micelle-forming agent in the separation electrolyte.[1–5] Otsuka et al.[4] have shown that in place of SDS cationic surfactants [here dodecyltrimethylammonium bromide (DTAB)] can also be successfully employed in MEKC. Their results showed that the separation selectivity in MEKC can be altered easily by variation of the structure of the added micelle-forming agent.

Since these pioneering studies, MEKC has matured into a separation technique that can be employed for the quantitation of noncharged solutes in complex matrices or for the improvement of the separation selectivity in CE. Comprehensive introductions to MEKC are those by Vindevogel and Sandra[6] and Terabe.[7] More recent reviews on current state-of-the-art in MEKC are those by Khaledi[8] and Muijselaar et al.[9]

The instrumentation used in MEKC is identical to that employed in CE (see **Capillary Electrophoresis**). Separation takes place in a fused-silica capillary with an inner diameter $< 100\,\mu m$ and a length mostly varying between 20 and 100 cm. The capillary is filled with the separation electrolyte and is immersed at both

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

ends in vessels filled with the same electrolyte. A high voltage (up to 35 kV) is applied between two electrodes immersed in the same vessels. The sample is injected directly into the first segment of the capillary. In order to avoid instrumental band broadening, detection is effected in a short segment of the capillary, mostly using photometric or fluorimetric detection. The migration of analyte zones is caused exclusively by electrokinetic effects. Hydrostatic liquid flow in the capillary must be avoided. The temperature of the capillary must be controlled, and this can be done either with a thermostated liquid flowing in a jacket around the separation capillary or by placing the capillary in a thermostated chamber.

2 THEORY OF SEPARATION

2.1 Separation Principles

In MEKC, the separation electrolyte contains the background electrolyte (mostly two inorganic salts forming a buffer system) and an ionic surfactant (anionic or cationic) at a concentration above the CMC dissolved in water or a water–organic solvent mixture. According to the theory of zone electrophoresis, during separation the field strength inside the capillary remains constant along the capillary, assuming that the dissolved analytes do not contribute significantly to the charge transport inside the capillary. Thus the field strength can be calculated from the ratio of the voltage (ca. 10–35 kV) to the total length of the capillary (ca. 20–100 cm).

A fraction of the surfactant monomers (depending on the total surfactant concentration and the CMC) dissolved in the separation electrolyte forms aggregates (micelles), which are charged in the case of ionic surfactants. In the case of the most popular surfactant in MEKC, SDS, the mean aggregation number in pure water at room temperature is 64.[10] There is a distribution of the aggregation number and this distribution is dependent on the temperature and on the composition of the surrounding medium.

As a result of electro-osmosis in bare fused-silica capillaries, the liquid in the capillary migrates with constant velocity towards the cathode. The direction of the electro-osmotic flow (EOF) is reversed in the case of a cationic surfactant in the separation electrolyte, because of the formation of hemimicelles at the capillary surface. The micelles are charged, thus have an electrophoretic mobility and migrate in the opposite direction to the EOF. Whether they are finally transported in the same direction as the EOF (but with lower velocity) or show an apparent velocity (apparent velocity of the micelles $\boldsymbol{v}_{MC}$ = electrophoretic velocity $\boldsymbol{v}_{ep}$ + electro-osmotic velocity $\boldsymbol{v}_{eo}$, addition of vectors) in the opposite direction depends on the relation of the absolute electrophoretic velocity $|\boldsymbol{v}_{ep}|$ of the micelles to the absolute velocity $|\boldsymbol{v}_{eo}|$ of the EOF. In all instances, $\boldsymbol{v}_{eo}$ and $\boldsymbol{v}_{ep}$ of the micelles have opposite directions provided that neither $\boldsymbol{v}_{eo}$ nor $\boldsymbol{v}_{ep}$ equals zero.

Dissolved compounds can be present either in the micellar phase or in the surrounding phase. Hence they are distributed between two phases migrating at different velocities (see Figure 1). In the theory of MEKC it is assumed that the velocity of the micelles is not altered by the incorporation of a solute. Consequently, a neutral solute will migrate with an apparent velocity identical with $\boldsymbol{v}_{eo}$ as long as it is dissolved in the surrounding phase and will migrate with $\boldsymbol{v}_{MC}$ as long as it is incorporated into a micelle. Its apparent migation velocity $\boldsymbol{v}_{mig}$ is between $\boldsymbol{v}_{eo}$ and $\boldsymbol{v}_{MC}$ depending on the distribution constant K_{MS} between these two phases (see Figure 2). K_{MS} here is defined as the concentration of solute in the micellar medium divided by the concentration of this solute in the surrounding medium with regard to a section of the capillary. A solute with $K_{MS} = 0$ (i.e. a very polar

Figure 1 Scheme illustrating separation mechanism in MEKC (anionic surfactant, normal elution mode).

Figure 2 Development of solute zones in a separation capillary, normal elution mode, neutral solutes, K_{MS}(solute 1) > K_{MS}(solute 2) > K_{MS}(solute 3).

compound) can therefore be used to trace $\boldsymbol{v}_{eo}$, and a solute with $K_{MS} \rightarrow \infty$ (i.e. a very nonpolar compound) can be employed to trace $\boldsymbol{v}_{MC}$.

In the case of solutes with an effective electrophoretic mobility different from zero (ions or solutes that are in a dissociation equilibrium with a charged species, i.e. acids or bases), separation is based not only on differences in K_{MS} but also on differences in the effective electrophoretic mobilities μ_{ep} of the solutes. In this case, separation can be regarded as electrophoresis modified by the presence of micelles.

2.2 Separation by Distribution

In MEKC it is possible to separate neutral solutes that differ only in K_{MS}. Figure 3 shows the separation of a mixture of 24 explosives (mostly nitrotoluenes) within 11 min. Separation by distribution between phases of different velocity is analogous to the separation process in chromatography. In analogy with chromatography, the phase surrounding the micellar phase is termed the mobile phase and the micellar phase is termed the pseudostationary phase, taking into consideration that only in rare cases is this phase virtually immobilized (in this case $\boldsymbol{v}_{eo} = -\boldsymbol{v}_{ep}$ of the micelles). In the normal elution mode $|\boldsymbol{v}_{MC}| < |\boldsymbol{v}_{eo}|$. In this mode, the micellar phase is retarded with respect to the surrounding, mostly aqueous phase.

For determining the retention factor k in MEKC, it has to be taken into consideration that the solute is transported not only by the mobile phase but also by the pseudostationary phase.

The retention factor k for a neutral solute is defined according to Equation (1):

$$k = \frac{t_{stat}}{t_{mob}} = \frac{t_R - t_{mob}}{t_{mob}} \tag{1}$$

where t_{stat} = fraction of time present in the stationary phase, t_{mob} = fraction of time present in the mobile phase and t_R = retention time. It is important to note that t_{mob} does not equal the elution time of a nonretarded marker and it has to be calculated from Equation (2):

$$\boldsymbol{v}_{mig} = \frac{t_{mob}}{t_R}\boldsymbol{v}_{eo} + \frac{t_R - t_{mob}}{t_R}\boldsymbol{v}_{MC} \tag{2}$$

Taking into consideration that $\boldsymbol{v}_{mig}$, $\boldsymbol{v}_{eo}$ and $\boldsymbol{v}_{MC}$ can be replaced by t_R/L, t_0/L and t_{MC}/L, respectively [t_0 = elution time of a nonretarded marker ($K_{MS} \rightarrow 0$), t_{MC} = elution time of a marker of the velocity of the micelles ($K_{MS} \rightarrow \infty$) and L = length of the capillary to the detector], Equations (1) and (2) can be transformed by rearrangement into Equation (3):

$$k = \frac{t_R - t_0}{t_0(1 - t_R/t_{MC})} \tag{3}$$

In order to obtain k, markers must be available that make it possible to determine t_0 and t_{MC}. These markers are often thiourea or methanol for the measurement of t_0 and timepidium bromide or quinine hydrochoride (for anionic micelles) or Sudan III for the measurement of t_{MC}.

Sep.*, **7**(2), 107–116 (1995), Copyright 1995 John Wiley & Sons Inc. Reprinted by permission of John Wiley & Sons, Inc.]

Chen et al.[11] have pointed out that in the presence of organic modifiers in the separation electrolyte, the determination of t_{MC} with a single hydrophobic compound as marker is unreliable. Therefore, the determination of t_{MC} based upon a homologous series has been proposed.[12] Kuzdzal et al.[13] proposed a procedure that can simultaneously determine t_0 and t_{MC} based on the retention times of several molecules in a homologous series. They employed the homologous series of methyl to *n*-pentyl *p*-hydroxybenzoates. In their approach, errors associated with the selection of appropriate markers can be avoided.

In the normal elution mode, t_R for a neutral solute can only have values between $t_0 (k = 0)$ and $t_{MC} (k \to \infty)$; the time span between t_0 and t_{MC} is also called the migration or elution window. This elution window limits seriously the peak capacity obtainable in MEKC. Often the ratio t_0/t_{MC} is used as a descriptor of the elution window, as it reflects the velocity ratio of the two phases. As t_0/t_{MC} decreases, the elution window increases.

If $\boldsymbol{v}_{eo} = 0$, then the analytes have to be transported by the micelles to the detector. Hence the EOF is not a prerequisite for MEKC. If $|\boldsymbol{v}_{ep}|$ of the micelles $> |\boldsymbol{v}_{eo}|$, then those solutes with $k > -t_{MC}/t_0$ have to be transported by the micelles to the detector.[6] For these solutes, the elution order is reversed with respect to the elution order obtained in the normal elution mode (the solute with the highest K_{MS} elutes first). The elution mode in which the solutes are transported with the micelles to the detector has therefore been termed reversed-migration micellar electrokinetic chromatography (RMMEKC). In contrast to the normal elution mode, in RMMEKC the elution window is not limited.

All the above conclusions are valid only in the case of neutral, noncharged solutes with an effective electrophoretic mobility $\mu_{ep} = 0$. If μ_{ep} is not negligible, then the apparent velocity of this solute in the mobile phase will be different from $\boldsymbol{v}_{eo}$. Hence Equation (2) has to be replaced by Equation (4):

$$\boldsymbol{v}_{mig} = \frac{t_{mob}}{t_R}(\boldsymbol{v}_{eo} + \mu_{ep}\boldsymbol{E}) + \frac{t_R - t_{mob}}{t_R}\boldsymbol{v}_{MC} \qquad (4)$$

where $\boldsymbol{E}$ = electric field strength.

The electrophoretic mobility has to be determined in a separate experiment with a separation electrolyte similar to that employed in MEKC without the presence of micelles. If μ_{ep} is known, it is possible to determine the true retention factor from the data already discussed for neutral solutes, replacing Equation (3) by Equation (5):[14]

$$k = \frac{t_R - t_{0M}}{t_{0M}(1 - t_R/t_{MC})} \qquad (5)$$

where t_{0M} = migration time of a solute in the absence of micelles.

It is important to note that t_{0M} is different from t_0. The magnitude t_{0M} has to be calculated from μ_{ep} of the solute, the field strength $\boldsymbol{E}$, the electro-osmotic velocity $\boldsymbol{v}_{eo}$ obtained with the micellar phase and the length $\boldsymbol{L}$ to the detector, according to Equation (6):

$$t_{0M} = \frac{\boldsymbol{L}}{\mu_{ep}\boldsymbol{E} + \boldsymbol{v}_{eo}} \qquad (6)$$

It should be noted, however, that, in MEKC, mobility data obtained with CE experiments have to be used with caution for calculating retention factors of charged solutes. Differences between true and calculated retention factors can arise from neglecting a fundamental difference between the composition of the mobile phase in MEKC and the electrolyte in CE, namely the presence of the surfactant monomer in the mobile phase at a concentration equal to the CMC in the case of MEKC.[15]

2.3 Separation by Electrophoresis

In the case of solutes with non-negligible μ_{ep}, the separation of two solutes is possible either if these solutes differ in the distribution constant K_{MS} or in μ_{ep}. Hence the addition of a surfactant to the separation electrolyte can be a valuable tool to effect the separation of charged solutes, if the selectivity obtained by electrophoresis is not sufficient, and also when electrophoresis remains the dominating effect.

From the viewpoint of electrophoresis, MEKC can be regarded as electrophoresis, with the micellar phase as an "interaction agent" influencing the effective mobility of the solutes.

For qualitative analysis (peak assignment), it can be useful to employ the pseudoeffective mobility $\tilde{\mu}_{ep}$[16] as a descriptor of a solute. This magnitude can be calculated from the elution time t_R of the solute and the elution time t_0 of a non-retained marker (Equation 7):

$$\boldsymbol{v}_{mig} = \frac{\boldsymbol{L}}{t_R} = \boldsymbol{v}_{eo} + (\tilde{\mu}_{ep}\boldsymbol{E}) = \frac{\boldsymbol{L}}{t_0} + (\tilde{\mu}_{ep}\boldsymbol{E}) \qquad (7)$$

The advantage of $\tilde{\mu}_{ep}$ calculated according to Equation (7) over k calculated according to Equation (5) is that neither t_{MC} nor the true effective mobility μ_{ep} have to be determined.

Ghowsi et al.[17] termed $\tilde{\mu}_{ep}$ the effective electrophoretic mobility of the solute. They defined the effective migration mobility of the solute $\tilde{\mu}_s$ as the summation of the effective electrophoretic mobility of the solute $\tilde{\mu}_{ep}$ and the electro-osmotic mobility μ_{eo} (Equation 8):

$$\tilde{\mu}_s = \tilde{\mu}_{ep} + \mu_{eo} \qquad (8)$$

It is important to note that also a neutral compound has a pseudoeffective mobility if k is different

from zero. For a neutral solute the effective electrophoretic mobility as defined in Equation (7) can therefore be described in terms of the retention factor k and the electrophoretic mobility of the micelle $\mu_{ep,MC}$[17] (Equation 9):

$$\tilde{\mu}_{ep} = \left(\frac{k}{1+k} \quad \mu_{ep,MC} \right. \tag{9}$$

For charged and non-charged solutes, $\tilde{\mu}_{ep}$ can be related to the retention time t_R via Equation (10):

$$t_R = \frac{LL_{tot}}{(\tilde{\mu}_{ep} + \mu_{eo})V} \tag{10}$$

where L = length to the detector, L_{tot} = total length and V = voltage. This equation is identical with that usually employed in CE and illustrates the impact of μ_{eo} and other physical parameters on the migration time of a solute.

3 RESOLUTION OPTIMIZATION

3.1 Resolution of a Peak Pair

For deriving the resolution equation for a pair of neutral solutes in the normal elution mode, Equation (3) has to be used instead of the term $k = (t_R - t_0)/t_0$ used in conventional chromatography. The resulting equation was derived by Terabe et al.[2] [Equation 11]:

$$R = \frac{\sqrt{N}}{4} \times \frac{\alpha - 1}{\alpha} \times \frac{k_2}{1 + k_2} \times \frac{1 - t_0/t_{MC}}{1 + (t_0/t_{MC})k_1} \tag{11}$$

where N = number of theoretical plates, α = selectivity factor and k_1 and k_2 = retention factors of the first and second solute (according to the elution order) ($\alpha = k_2/k_1$).

In contrast to conventional liquid chromatography (LC), the resolution is dependent not only on the chromatographic efficiency, the selectivity and the retention factor, but also on the ratio t_0/t_{MC}, which in the normal elution mode is smaller than unity. Consequently, in MEKC in the normal elution mode at identical N, α, k_1, and k_2, the resulting resolution is always smaller than that obtainable with an immobilized stationary phase. The impact of t_0/t_{MC} on the resolution in comparison with conventional chromatography ($t_0/t_{MC} = 0$) is illustrated in Figure 4, where $f(k)$ is plotted against k, approximating $k_1 = k_2 = k$. The term $f(k)$ corresponds to the last two terms of Equation (11). It is also called the retention term and consists of the two terms containing the retention factor (Equation 12):

$$f(k) = \frac{k}{1+k} \times \frac{1 - t_0/t_{MC}}{1 + (t_0/t_{MC})k} \tag{12}$$

Figure 4 Dependence of $f(k)$ on the retention factor k for different values of t_0/t_{MC} (given on each curve). (Reprinted with permission from S. Terabe, K. Otsuka, T. Ando, *Anal. Chem.*, **57**(4), 834–841 (1985), Copyright 1985 American Chemical Society.)

With Figure 4, Terabe et al.[2] have also shown that the resolution does not increase steadily with increase in the mean retention factor for the solutes to be separated (provided that N, α and t_0/t_{MC} are constant), but reaches a maximum. By differentiation of Equation (12) with respect to k and setting the resulting expression equal to zero, Foley[18] calculated that maximum resolution is obtained for a mean retention factor $\bar{k} = \sqrt{t_{MC}/t_0}$.

In the case of charged solutes, the resolution is affected by both differences in the effective electrophoretic mobilities of the solutes and differences in the retention factor. A resolution equation applicable to charged solutes was derived by Corstjens et al.[19] This equation relates the resolution for a peak pair (normal elution mode) to the capacity factors and the t_{M0} values (see Equations 5 and 6). It can be used to gain insight into the separation mechanisms involved.

Zhang et al.[20] presented a classification scheme that is restricted to the separation of neutral solutes. They defined the phase velocity ratio P_r according to Equation (13):

$$P_r = \frac{t_{MC}}{t_0} \tag{13}$$

With this introduced magnitude, Equation (3) can be rewritten as Equation (14):

$$t_R = t_0(k+1)\frac{P_r}{k + P_r} \tag{14}$$

It is important to note that Equation (14) is valid for any value of P_r. P_r can be negative based on the definition that the velocity is positive when the migration is towards the negative electrode and negative when it is towards the positive electrode.[2] Hence a negative t_{MC} or t_0 indicates that the micellar phase or the surrounding medium migrates towards the positive electrode. The same holds true for the migration time t_R. The absolute value of t_R indicates the elution time of a solute, *if the voltage is suitable*.

According to the value of P_r, MEKC has been classified by Zhang et al. into eight cases, that can be simplified to six cases: (1) $P_r = 0$, (2) $0 < P_r < 1$, (3) $P_r = 1$, (4) $1 < P_r < \infty$, (5) $P_r \to \infty$ or $-\infty$ and (6) $-\infty < P_r < 0$.

The last term of Equation (11) corresponds to the column availability A_{co} introduced by Zhang et al.[20] (Equation 15):

$$A_{co} = \frac{P_r - 1}{P_r + k_1} \tag{15}$$

The normal elution mode corresponds to case (4). In this case $0 < A_{co} < 1$ (see Figure 4). Case (2) would represent the inverted normal elution mode, if a physical realization were possible. Both phases migrate in the same direction, but the micelles migrate faster than the EOF. Case (5) corresponds to conventional chromatography with a mobile and a stationary phase. In this case $A_{co} = 1$. Case (1) corresponds to conventional chromatography if the micellar phase is regarded as the mobile phase and the surrounding phase as the stationary phase. As the micelles are in this case the nonpolar phase, this would correspond to normal-phase LC. In case (3), no separation is obtained, as both phases migrate with the same velocity, $A_{co} = 0$. In case (6), the column availability can be larger than unity. However, in case (6) the migration direction of a solute (towards the cathodic or the anodic end) depends on the retention factor. Case (6) has therefore also been termed the restricted elution mode for $k < -t_{MC}/t_0$.[6] For $k > -t_{MC}/t_0$ it is identical with RMMEKC defined in section 2.2.

3.2 Adjustment of Retention Factors

As depicted in Figure 4, one optimization strategy for the separation of non-charged solutes with MEKC in the normal elution mode is to bring the retention factors of the solutes to be separated into the optimum range. This can be done by:

- variation of the pseudostationary phase/mobile phase phase ratio;
- employing a different surfactant;
- adding a modifier to the separation electrolyte that influences the distribution constant K_{MS}.

The retention factor k is related to the pseudostationary phase/mobile phase phase ratio by Equation (16):

$$k = K_{MS}\frac{V_{mic}}{V_{sur}} \tag{16}$$

where V_{mic} = volume of micellar phase and V_{sur} = volume of surrounding medium. V_{mic} can be determined from the total concentration of surfactant c_{tot} minus the concentration of surfactant present as monomers (this corresponds to the CMC) and the molar volume $\tilde{V}_{surf}$ of surfactant present in the micellar phase[2] (Equation 17):

$$\frac{V_{mic}}{V_{sur}} = \frac{\tilde{V}_{surf}(c_{tot} - CMC)}{1 - \tilde{V}_{surf}(c_{tot} - CMC)} \tag{17}$$

If $c_{tot} - CMC$ is small, $1 - \tilde{V}_{surf}(c_{tot} - CMC)$ can be approximated by unity. Hence there is a linear relationship between the total surfactant concentration and the retention factor[2] (Equation 18):

$$k = K_{MS}\tilde{V}_{surf}(c_{tot} - CMC) \tag{18}$$

By employing Equation (3) for the calculation of k for neutral solutes from experimental data, the validity of the assumptions made for Equation (18) can be verified experimentally.[2] In Figure 5, the dependence of the retention factor for *p*-nitrotoluene on the total concentration of the surfactant SDS in the separation electrolyte is given for different concentrations of urea as modifier. In all cases straight lines are obtained. The intersection of the regression line with the x-axis at $k = 0$ corresponds to the CMC.

The practical range of surfactant concentration is limited. The lower usable concentration limit is determined by the need to generate a micellar phase, hence it must be

Figure 5 Retention factor k for *p*-nitrotoluene as a function of the concentration of the surfactant SDS in the separation electrolyte. c(Urea) = (○) 0; (×) 1; (∗) 2; ( ) 3; (+) 4 mol L^{-1}. Background electrolyte: 30 mmol L^{-1} disodium tetraborate.

considerably above the CMC. A too low volume of micellar phase might cause band broadening due to overload of the pseudostationary phase. The upper concentration limit is given by the solubility of the surfactant in the surrounding phase (precipitation of surfactant must be avoided) and by limitations concerning the electric current tolerated by the experimental set-up. The addition of an ionic surfactant to the separation electrolyte increases considerably its specific electric conductivity. Consequently, instrumental parameters such as the inner diameter of the capillary, total length of capillary and efficiency of the thermostatting system can have an impact on the upper concentration limit.

In the case of non-polar analytes it might be impossible to bring the retention factors of the solutes to be separated into the optimum range only by varying the total surfactant concentration. In these cases it is possible to use a modifier, mostly an organic solvent[21,22] or urea,[23,24] or urea and an organic modifier simultaneously.[25] The modifier reduces the distribution constant K_{MS}. In Figure 5, the slope of the regression line decreases with increasing content of urea in the separation electrolyte. As the x-axis intercept corresponds to the CMC and there is virtually no dependence of the CMC on the modifier concentration, assumptions are corroborated that in the case of urea as modifier there is only a small impact of the urea concentration on the CMC of SDS. Only a few data are available on the impact of the modifier on the CMC or on the micelle structure (i.e. mean aggregation number, distribution of aggregation number, shape). There is an indication that the addition of urea and of acetonitrile (below a critical concentration) does not alter the CMC of SDS, largely in electrolytes that are usually employed in MEKC.[22,24] Consequently, it can be assumed in those cases that the phase ratio can be approximated to be constant independent of the modifier content.

The large impact of organic modifiers on the retention factors is illustrated in Figure 6(a) and (b), comparing the MEKC separation of dansylated alkylamines effected with a separation buffer containing no organic modifier and effected under identical experimental conditions with a separation buffer containing a volume concentration of acetonitrile of 15% (v/v) and a concentration of urea of 4.1 mol L^{-1}.[25] The concentration of the surfactant SDS was kept constant at 20 mmol L^{-1}. The retention factor of dansylated 1-aminohexane can be reduced (at a constant surfactant concentration) from 185 obtained under the conditions of Figure 6(a) to 1.26 with a separation buffer containing a concentration of acetonitrile of 15% (v/v) and a concentration of urea of 5.0 mol L^{-1}.[25]

The retention factors of solutes can also be drastically reduced by adding cyclodextrins to the separation electrolyte. Terabe et al.[26] termed this variant of MEKC

Figure 6 Separation of dansylated aliphatic amines (a) without addition of organic modifiers and (b) with 15% acetonitrile and 4.1 mol L^{-1} urea in the separation electrolyte. Composition of separation electrolyte: 10 mmol L^{-1} disodium tetraborate, 10 mmol L^{-1} boric acid, 20 mmol L^{-1} SDS; photometric detection, $\lambda = 254$ nm; $U = 25$ kV. Capillary dimensions: 75 µm inner diameter, 465 mm total length. (1) 2-aminoethanol, (2) methylamine, (3) ethylamine, (4) morpholine, (5) 2-aminopropane, (6) diethylamine, (7) 1-amino-2-methylpropane, (8) 1-aminobutane, (9) 1-amino-3-methylbutane, (10) 1-aminopentane, (11) 1-aminohexane. cyclodextrin-modified micellar electrokinetic chromatography (CDMEKC). With this method they were even able to separate chlorinated benzene congeners and other highly hydrophobic solutes.

A third possibility for varying the retention factor is the selection of the surfactant used. The micelles or multimers of bile salts (cholates and taurocholates) show a solubilizing power that is usually much smaller than that of SDS. They have therefore been employed for the separation of very nonpolar solutes.[27] Their chiral properties have also been used for enantiomeric resolution.[28]

3.3 Widening of the Migration Window

The considerations outlined in section 3.1 have shown the strong impact of the ratio t_{MC}/t_0 (also termed the phase velocity ratio, P_r) on the column availability A_{co}, and consequently the resolution obtainable [Equation 19]:

$$R = \frac{\sqrt{N}}{4} \times \frac{\alpha - 1}{\alpha} \times \frac{k_2}{1 + k_2} A_{co} \qquad (19)$$

Equation (19) corresponds to Equation (11).

In the normal elution mode for neutral solutes, t_R is restricted to the migration or elution window with the limits t_0 and t_{MC}. From Equation (11) and Figure 4 it can be deduced that in this mode the resolution will be improved if the ratio t_0/t_{MC} is lowered. The limited migration window limits also the peak capacity of the separation system (peak capactity = maximum number of substances that can be separated by a system). For rapid separations, however, a small resolution window [corresponding to a steep gradient in gradient elution high-performance liquid chromatography (HPLC)] can also have advantages.

An overview on parameters controlling the elution window in MEKC with an anionic surfactant (mostly SDS) as micelle-forming agent was given by Muijselaar et al.[29] These parameters include buffer pH, ionic strength, capillary surface modifications, alkyl chain length of the surfactant, surfactant concentration and organic modifiers. Principally, two effects can be used to widen the migration window: (1) increase in the electrophoretic velocity of the micelles and (2) reduction of the electro-osmotic velocity. Although effect (1) has advantages over (2) as it widens the migration window without prolonging the hold-up time of the system, thus increasing the analysis time only slightly, there are difficulties in its physical realization. Hence effect (2) is mostly employed for improving the migration window. It should be noted, however, that by addition of urea to a separation electrolyte containing SDS it is possible to widen the migration window significantly, while t_0 is only marginally increased.[23,24] Other organic modifiers (e.g. methanol and acetonitrile) also widen the migration window.[29,30] These modifiers, however, also have a large impact on the retention factors of the solutes. They are, therefore, predominantly used for adjusting retention factors.

When a separation electrolyte is used that contains an anionic surfactant as micelle-forming agent, the electrokinetic potential and consequently the electro-osmotic velocity is not influenced by the formation of hemimicelles on the negatively charged fused-silica surface. In this case the electro-osmotic mobility is largely dependent on the pH, whereas the electrophoretic mobility of the micelles can be expected to be virtually independent of the pH.[29] Thus in MEKC with an anionic surfactant the pH is a very powerful tool for regulating t_{MC}/t_0 at the expense of increasing the hold-up time. Otsuka and Terabe[31] have shown that with SDS as micelle-forming agent the direction of the apparent velocity of the micelles is changed at pH 5.0. Whereas at high pH the absolute electrophoretic mobility $|\mu_{ep}|$ of the micelles is smaller than the absolute electro-osmotic mobility $|\mu_{eo}|$ corresponding to the normal elution mode, at low pH $|\mu_{ep}|$ is larger than $|\mu_{eo}|$ corresponding to the restricted elution mode or reversed elution mode.[31,32]

Janini et al.[33] have shown that coating of the inner surface of the fused-silica capillary with a linear polyacrylamide can be used to reduce drastically the electro-osmotic mobility. In this case the reversed elution mode can also be obtained at higher pH.

When a cationic surfactant is used as micelle-forming agent in MEKC, μ_{eo} is reversed by the hemimicelles that are formed by the surfactant monomers on the fused-silica surface. Hemimicelles are aggregates of surfactant monomers that are adsorbed on the solid at the solid–liquid interface.[34]

Currently, cationic surfactants are rarely employed in MEKC separations, partly because in the normal elution mode the migration window is generally much smaller when using an alkyltrimethylammonium bromide as cationic surfactant than the migration window that can be obtained with SDS as the micelle-forming agent.[4] Cationic surfactants, however, have a complementary selectivity to other anionic surfactants.[35,36] Moreover, there is indication that cationic surfactants can have advantages over anionic surfactants concerning repeatability in routine analysis.[37] However, means of improving the migration window in MEKC with cationic surfactants have scarcely been investigated so far.

The pH dependence in the presence of a cationic surfactant differs strongly from that observed with an anionic surfactant. Crosby and ElRassi[38] determined the dependence of μ_{eo} on pH with a separation electrolyte containing hexadecyltrimethylammonium bromide (CTAB). Under the conditions of their measurements, the width of the migration window remained virtually unchanged as the pH was varied between 4.5 and 9.0.

In order to widen the migration window, additives (e.g. inorganic salts with divalent metal cations) to the separation electrolyte can be used that are selectively adsorbed on the fused-silica surface, competing with the surfactant monomers for positions in the electric double layer.[39,40] The result is a reduction in the electro-osmotic mobility μ_{eo}. If μ_{eo} is decreased while the electrophoretic mobility μ_{ep} of the micelles is maintained, the result will be an improvement in the migration window. In Figure 7(a)

Figure 7 Separation of nitrotoluenes with a separation electrolyte containing (a) 0 and (b) 30 mmol L^{-1} $CaCl_2$. Composition of separation electrolyte: 10 mmol L^{-1} sodium acetate, 10 mmol L^{-1} acetic acid, 40 mmol L^{-1} TTAB, pH = 4.6; photometric detection, $\lambda = 254$ nm; $U = 25$ kV. Capillary dimensions: 75 µm inner diameter, 565 mm total length. (1) 2,4,6-trinitrotoluene, (2) 2,5-dinitrotoluene, (3) 2,4-dinitrotoluene, (4) 2,6-dinitrotoluene, (5) 3,4-dinitrotoluene, (6) 2,3-dinitrotoluene. (Reprinted from A. Dworschak, U. Pyell, 'Widening of the Elution Window in Micellar Electrokinetic Chromatography with Cationic Surfactants. I. Selection of Surfactant, Variation of pH and Addition of Organic Modifiers or Inorganic Metal Salts', *J. Chromatogr. A*, **848**, 387–400 (1999), Copyright 1999, with permission from Elsevier Science.)

and (b) the effect of the addition of $CaCl_2$ to the separation electrolyte on the separation of nitrotoluenes by MEKC with tetradecyltrimethylammonium bromide (TTAB) is shown. While the retention factors are kept virtually constant, there is a large improvement in the resolution due to deceleration of the EOF, resulting in an increase in the ratio t_{MC}/t_0 and improvement of the column availability factor.

3.4 Selectivity

A major advantage of MEKC is its flexibility. The composition of the separation electrolyte and, in particular, the pseudostationary phase can easily be changed by rinsing the capillary. Hence MEKC is more flexible than a chromatographic technique with an immobilized stationary phase. The composition of the mobile phase and the composition of the pseudostationary phase can easily be adapted to the respective separation problem.

In MEKC, the selectivity for separations of neutral solutes is mainly dependent on the surfactant system used. Various types of surfactants have been used in MEKC over the past 10 years: charged surfactants (anionic or cationic), non-ionic and zwitterionic surfactants (see Table 1). In order to separate noncharged solutes, charged surfactants must be used. Surfactants with a zero net charge can be used along with an ionic surfactant as selectivity modifier forming mixed micelles with the charged moities. Nonionic and zwitterionic surfactants can also be used alone to modify the selectivity for the separation of charged solutes.

Table 1 Surfactants employed in MEKC and their CMC determined in distilled water at ambient temperature

Surfactant	CMC (mmol L^{-1})
Anionic surfactants:	
Sodium decyl sulfate	33[a]
SDS	8.2[a]
Sodium tetradecyl sulfate	2.1[a]
Sodium hexadecyl sulfate	0.45[a]
Sodium *N*-lauroyl-*N*-methyl-β-alaninate (ALE)	9.8[b] (40 °C)
Sodium *N*-lauroyl-*N*-methyltaurate (LMT)	8.7[b] (35 °C)
Lithium perfluorooctanesulfonate (LIPFOS)	6.7[c]
Bile salts:	
SC	13[d]
Sodium deoxycholate (SDC)	10[d]
Sodium taurocholate (STC)	10[d]
Sodium taurodeoxycholate (STDC)	6[d]
Cationic surfactants:	
DTAB	16[e] (25 °C)
TTAB	3.6[e] (25 °C)
CTAB	0.92[e] (25 °C)
Nonionic surfactant:	
Brij® 35	0.1[d]

[e] Data from Crosby.[38]

SC, sodium cholate; Brij® 35, polyoxyethylene(23)dodecyl ether.

The fundamental importance of selectivity for resolution is represented by the presence of the selectivity factor α in Equation (11). For neutral solutes the choice of surfactant is the most important consideration in optimizing selectivity. Poole and Poole[41] have shown that the experimental parameters surfactant concentration, buffer concentration, buffer pH, temperature and choice of buffer have little influence on the selectivity (for neutral solutes and SC as surfactant). There is some alteration in the selectivity with organic modifiers in the separation electrolyte. However, the choice of organic solvent (5%, v/v) as modifier (methanol, acetonitrile, tetrahydrofuran, propan-2-ol) seems to be virtually without influence on the selectivity.

For rapid method development in MEKC, it is therefore highly desirable to have a set of surfactants with complementary selectivity. The following constraints have to be respected: (1) their Krafft points must be lower than ambient temperature; (2) their CMC in the separation electrolyte (different from that in pure water) should not exceed 20–30 mmol L^{-1}; (3) their solubility in aqueous buffers at ambient temperature must be sufficient. These constraints can mostly be fulfilled by only one member of a homologous series with varying alkyl chain length (see Table 1).

Yang and Khaledi[42] and Yang et al.[43] employed linear solvation energy relationships (Kamlet–Taft solvatochromic model) in order to make an attempt to classify surfactants according to the type of solute–surfactant interaction. They concluded that hydrogen-bonding interactions play a major role in providing different chemical selectivity among the five surfactant systems that they investigated.

Poole and Poole[41] employed the solvation parameter model, that is in use in areas of retention modeling in chromatography, in order to characterize the surfactant selectivity in MEKC. In this model the solvation process is described in terms of fundamental intermolecular interactions with solute or solvent properties determined from equilibrium processes. Employing data obtained by applying this model, they suggested a working list for surfactants for selectivity optimization in MEKC: SDS, SC, lithium perfluoro-octanesulfonate, *N*-dodecanoyl-*N*-methyltaurine and TTAB.[44]

Muijselaar et al.[45] introduced the retention index concept for application in MEKC. They defined the retention index I of a solute according to Equation (20):

$$I = 100z + 100\frac{\log\left(\frac{t_s - t_0}{t_{MC} - t_s}\right) - \log\left(\frac{t_z - t_0}{t_{MC} - t_z}\right)}{\log\left(\frac{t_{z+1} - t_0}{t_{MC} - t_{z+1}}\right) - \log\left(\frac{t_z - t_0}{t_{MC} - t_z}\right)} \quad (20)$$

where z = number of carbon atoms in a member of a homologous series eluted before the solute, t_s = elution time of a solute, t_0 = hold-up time, t_{MC} = migration time of the micelles, t_z = elution time of a neighboring member of a homologous series (eluted before the solute) and t_{z+1} = elution time of a neighboring member of a homologous series (eluted after the solute). The retention index defined according to Equation (20) is not dependent on the phase ratio, i.e. it is independent of the surfactant concentration. Alkylbenzenes and alkyl aryl ketones can be used as retention index standards in MEKC. The retention index is useful as a parameter for peak identification. In analogy with the Rohrschneider–McReynolds scale in gas chromatography (GC), the retention index can be also employed for the characterization of pseudostationary phases.[46]

Fine tuning of the selectivity can be performed by employing mixed micelles. To this end, Little and Foley[47] employed a mixed micellar system consisting of SDS and Brij® 35. The variation of selectivity with composition for a mixed-micellar buffer has been studied by employing the solvation parameter model.[48] The change in selectivity associated with the addition of Brij® 35 to separation electrolytes containing SDS has been reported by Rasmussen et al.[49] The main disadvantage of this approach is an unfavorable narrowing of the migration window in the normal elution mode caused by the integration of the nonionic surfactant into the anionic micelles, thus reducing the electrophoretic mobility of the micelles. As can be seen from Equation (11), this effect (increase in t_0/t_{MC}) can counteract the resolution improvement through increase in α.

A general overview on techniques that can be employed to manipulate the selectivity in MEKC was given by Terabe.[50] These techniques comprise the choice of the surfactant and the use of mixed micelles, but also additives such as ion-pair reagents, urea, organic solvents and metal ions. For ionizable solutes a strong impact on selectivity is given by the pH of the separation electrolyte. An extensive investigation on the migration behavior of acidic solutes has been presented by Khaledi et al.[51] Their phenomenological approach assumes that the parameters, retention factor and electrophoretic mobility, of an acidic solute are the weighted average of the parameter of the solute in the dissociated and the undissociated forms. By variation of the pH, the dissociation equilibrium is influenced, and thus also the effective retention factor and the effective electrophoretic mobility. Khaledi et al. developed equations describing the relationships between the two migration parameters – retention factor and mobility – on the two experimental parameters: pH and surfactant concentration. The same approach can be employed for an understanding of the dependence of the migration behavior of basic solutes on pH.[52]

If basic solutes are separated in MEKC with an anionic surfactant or acidic solutes are separated in MEKC with a

cationic surfactant, not only the acid–base equilibrium but also ion-pair formation equilibrium between the charged species and the monomer surfactants and interaction between the charged species and the micellar phase have to be taken into consideration. Ionic species exhibit a strong interaction with a surfactant having the opposite charge and have a measurable retention factor due to interaction with the oppositely charged micellar phase.[53]

For the separation of acidic solutes (partly or fully dissociated) or basic solutes (partly or fully protonated), the selectivity can be completely altered (at constant pH) if a cationic surfactant is used instead of an anionic surfactant.[4] Nishi et al.[5] have demonstrated that the selectivity can also be effectively manipulated in MEKC with an anionic surfactant (separation of carboxylic acids and cationic and zwitterionic substances) by addition of an ion-pair reagent (tetraalkylammonium bromide). By addition of the ion-pair reagent to the separation electrolyte containing SDS as micelle-forming agent, the migration time of cationic solutes is decreased and the migration time of anionic solutes, in contrast, is increased at about constant electro-osmotic velocity.

3.5 Efficiency

The efficiency of a chromatographic system is quantified by the number of theoretical plates per column, N. A high efficiency is important for the resolution of closely related compounds [see Equation 11], for rapid separations and for obtaining a sufficiently high peak capacity. MEKC can be characterized as a separation method with inherently high efficiency – one of its main advantages over conventional chromatographic techniques. The number of theoretical plates per capillary (length to the detector 50–70 cm) obtained in MEKC for retarded ($k = 1–5$) neutral solutes under routine conditions is about 200 000–300 000.[54,55]

Terabe et al.[54] have studied in detail for MEKC the band-broadening phenomena that occur in the separation capillary during a run. These phenomena have to be divided into two groups: the extra-column and the in-column effects. Extra-column effects comprise the injection volume, the cell volume of the detection part of the capillary, the time constant of the detector and the sampling rate of the data system or the response of the recorder pen. With suitable injected plug length and adequate in-column detection, extra-column effects can be kept low.

The causes of in-column band broadening can be ascribed to five mechanisms: longitudinal diffusion, sorption–desorption kinetics, intermicelle mass transfer, radial temperature gradient effects and electrophoretic dispersion of the micelles (heterogeneity in micelle mobilities). At slow velocity of the solute zones, longitudinal diffusion is the dominant factor, whereas at higher velocities sorption–desorption kinetics and heterogeneity in micelle mobilities become significant factors. For separations in the normal elution mode, Terabe et al.[54] recommend working with an electro-osmotic velocity $>1\,\mathrm{mm\,s^{-1}}$ and keeping the retention factors to <5.

The influence of the surfactant concentration on efficiency is controversially discussed in the literature.[54,56,57] Yu et al.[57] did not obtain a significant dependence of N on the SDS concentration of the separation electrolyte for moderately retarded solutes in the concentration range $15–100\,\mathrm{mmol\,L^{-1}}$. They showed that it is possible in MEKC to obtain an efficiency that is limited only by the injected sample plug length and longitudinal diffusion. At very high electro-osmotic velocity, factors corresponding to the resistance in mass transfer known for conventional chromatography are dominant, thus resulting in a drastic decrease in N with increasing electro-osmotic velocity.[55,57,58]

In order to use the high efficiency obtainable in MEKC, band broadening due to inadequate buffer leveling has to be avoided. If the buffer levels in the inlet and the outlet vessel are not identical, a laminar flow in the capillary independent of the EOF will be induced (siphoning effect). In theoretical considerations, a perfect plug-like flow is assumed. This assumption is not fulfilled in the case of siphoning effects. Siphoning effects can result in a dramatic decrease in efficiency. The same holds true for band broadening due to solute–wall interactions. Muijselaar et al.[29] reported an intolerable decrease in efficiency when employing coated capillaries in MEKC. Band-broadening effects due to solute–wall interactions can also be due to fouling of the capillary.

3.6 Computer-assisted Resolution Optimization

Separations in MEKC are characterized by a large number of parameters and therefore empirical method development can be very difficult and time-consuming. Further complications can arise from the mutual interaction of these parameters affecting the separation. Computer-assisted resolution optimization schemes can be regarded as a tool in method development that gives guidelines for selecting the significant parameters, and that makes it possible to find suitable conditions after a minimum of initial experiments. Although for HPLC several optimization schemes have been published, these approaches at least require substantial modification before they can be used to optimize an MEKC separation.

An exhaustive and instructive introduction into this area was given by Khaledi et al.[59] In a review by Corstjens et al.,[60] typical features of optimization

strategies applicable to MEKC are discussed. A more recent review on optimization strategies developed for MEKC was given by Khaledi.[8]

Approaches based on physicochemical models have to be distinguished from approaches based on empirical models. Although the use of physicochemical models is always preferred, since an in-depth understanding of the underlying equilibria can be achieved, such an approach is not always feasible, as numerous experiments can be required to determine the relevant constants in the equations with sufficient accuracy.

Smith and Khaledi[61] and Quang et al.[62] developed a strategy to model the migration behavior on the basis of physicochemical parameters estimated from model fitting on the basis of few initial experiments. With their approach, the rapid optimization of pH and surfactant concentration is possible. The linear relation between the retention factor and the concentration of surfactant [see Equation 18 and Figure 5] was used by Pyell and Bütehorn[24] to develop a strategy for the optimization of the surfactant concentration (one-parameter optimization) on the basis of only two initial experiments. This approach has been extended to the simultaneous optimization of the surfactant and the modifier concentration for urea[63] and acetonitrile[22] as modifier.

For certain parameters (e.g. temperature), physicochemical models are unavailable. In this case, empirical (also called statistical) models are useful in minimizing the number of experiments required to find suitable conditions. In addition to factor-based methods,[64] a simplex algorithm,[65] the overlapping resolution mapping scheme[66] and the iterative regression strategy[67] have been applied in MEKC. Wiedmer et al.[68] optimized the composition of a separation electrolyte containing SDS and SC by using empirical quadratic regression models.

3.7 Sample Stacking/Sweeping

Because of the small detection cell volume, which has to be chosen to avoid radial temperature gradient effects due to Joule heating (limitation of the inner diameter of the separation capillary) and to avoid extra-column band broadening (limitation of the length of the detection cell), MEKC methods often exhibit detection limits that are one or more orders of magnitude lower than in corresponding HPLC methods. The disadvantages due to the limitations of the detection volume, however, can possibly be overcome by on-line sample concentration techniques, which are not applicable in HPLC.

One on-line technique applicable in MEKC is stacking. Sample stacking was initially developed for charged analytes in CE. It is based on differences in the electric conductivity of bordering zones, resulting in differences in the effective migration mobilities $\tilde{\mu}_s$ of the solutes, following from the Kohlrausch regulating function. If the sample solution has a conductivity much lower than that of the separation electrolyte, the electric field strength in the sample zone will be significantly higher than in other parts of the capillary. As the ions move across this boundary that separates regions of different electric field strength, they will be focused in a zone narrower than the initially injected sample zone. Sample stacking techniques developed for CE can be also applied for the MEKC separation of charged solutes.

According to Equation (9), a neutral compound also has a pseudoeffective mobility if k is different from zero. Hence sample stacking is possible with neutral solutes in MEKC, provided that the solutes exhibit an effective migration mobility $\tilde{\mu}_s$ due to interaction with a pseudostationary phase during the stacking process.[69–72]

A second mechanism suitable for on-line concentration of neutral analytes in MEKC is sweeping. Sweeping is a term that was coined by Quirino and Terabe, defined as 'the picking and accumulation of analytes by the pseudostationary phase that fills the sample zone during application of voltage'.[73,74] It occurs whenever the sample matrix is devoid of pseudostationary phase and it does not need a lower electric conductivity in the sample solution than in the separation electrolyte. Sweeping can be compared to injection zone focusing processes occuring in conventional chromatography, when the sample solution is injected into the separation column. As has been shown by Quirino and Terabe,[73,74] in the reversed elution mode this concentration effect is effective, in particular, with solutes with very high retention factors. An on-line concentration effect that has been reported by Gilges[75] for the determination of impurities in a drug substance by MEKC in the normal elution mode is obviously also due to sweeping.

Theoretically, it should be possible to combine stacking and sweeping by preparing the sample in a solution with low electric conductivity containing no pseudostationary phase. The full potential of on-line concentration techniques in MEKC has not yet been pushed to its limit. On-line concentration techniques will play a key role in extending the applicability of MEKC to trace analysis and making this technique competitive in comparison with HPLC.

4 APPLICATION

4.1 Sample Preparation and Figures of Merit

There is no stationary phase in MEKC that can be fouled by irreversible sorption of matrix constituents, as the

separation electrolyte, containing the pseudostationary phase, is exchanged by rinsing procedures after each run. However, irreversible sorption of matrix constituents on the inner capillary wall must be avoided, as it results in an irreproducibility of migration times depending on the status of the capillary surface. In order to avoid blocking of the capillary by injected particles, samples should be filtered with a membrane filter prior to injection.

Because of the absence of a stationary phase and solubilization of matrix constituents by the micellar phase, direct sample injection is possible in many cases. In these cases, the highly efficient separation system must provide sufficient separation of the solutes of interest from interfering matrix constituents. In the case of direct sample injection of 'dirty' samples, often specific rinsing procedures between the runs have to be applied in order to maintain the repeatability of migration times.[76]

With proper rinsing procedures and suitable thermostating of the capillary, the relative standard deviation of the retention times (intra-day) for detectable solutes in real samples is generally <1%.[76–79] In practice, because of electrode reactions, buffer depletion can occur, resulting in a drift of the pH of the separation electrolyte and other parameters. This problem, however, can easily be overcome by a frequent change of the separation electrolyte. If the composition of the sample solution deviates strongly from that of the separation electrolyte (e.g. much higher content of organic modifier in the sample than in the separation electrolyte), peak splitting, retention time shifts and peak deformations (fronting, tailing, broadening) can result.[16,78,80] Consequently, mismatch of the composition of the sample solution with the composition of the separation electrolyte has to be avoided or must be taken into account for the preparation of standard solutions.

In some publications, figures of merit obtainable with an HPLC method are compared with those that can be obtained with an MEKC method: determination of nitroaromatic compounds in soil,[79] phospholipids in lecithin,[81] phenolic compounds in spiritous liquor,[77] impurities in a pharmaceutical compound[75] and pesticides in aqueous matrix.[82] In all these comparative studies photometric detection was employed. Although higher than those in HPLC, the limits of detection obtained in MEKC were fit for purpose.

Data obtained by HPLC agreed well with those given by MEKC.[77,79,81] The precision of the determination expressed as relative standard deviation for the determined peak area is strongly dependent on the method parameters. With an internal standard (in order to eliminate imprecision in sample injection), relative standard deviations for the peak areas normalized on the peak area of an internal standard of <1% can be obtained.[78] With real samples (coffee, spiritous liquor) and suitable rinsing of the capillary between runs, relative standard deviations for the peak areas determined for consecutive runs (without internal standard) as low as 1–1.5% have been reported. In other studies, a significantly higher relative standard deviation for the (absolute) peak areas was obtained for the MEKC method in comparison with HPLC.[79,81] However, the MEKC method can offer advantages over conventional HPLC methods in the routine analysis of real samples because of the higher peak capacity, higher efficiency and a selectivity different from that obtained in RPHPLC with conventional stationary phases: improved selectivity, higher accuracy due to baseline separation of adjacent peaks, separation of very closely related compounds (higher information content) and short run times.[75,81]

4.2 Analysis of Drugs

Nishi and Terabe[83] showed in a review on drug analysis by MEKC that most types of analysis in this field can be

Figure 8 Three-dimensional plot for the MEKC analysis of (a) a directly injected and (b) a cleaned-up serum sample from a patient receiving theophylline pharmacotherapy. Peak assignment: (1) theobromine (internal standard); (4) theophylline; (10) uric acid. Composition of separation electrolyte: 6 mmol L^{-1} disodium tetraborate, 10 mmol L^{-1} disodium phosphate, 75 mmol L^{-1} SDS, pH = 9; detection with photodiode detector; $U = 25$ kV. (Reprinted from W. Thormann, A. Minger, S. Molteni, J. Caslavska, P. Gebauer, 'Determination of Substituted Purines in Body Fluids by Micellar Electrokinetic Capillary Chromatography with Direct Sample Injection', *J. Chromatogr.*, **593**, 275–288 (1992), Copyright 1992, with permission from Elsevier Science.)

performed by using MEKC. These applications include purity testing of drugs, assay of drugs, determination of drugs in biological fluids, including the direct injection method, and separation of complex mixtures. Nishi and Terabe[83] highlighted that MEKC is, in particular, a powerful method for the separation of complex mixtures such as natural products and crude drugs because of its high peak capacity.

MEKC with an ionic surfactant allows the direct injection of proteinaceous fluids, such as serum. Most of the work on the determination of drugs in biological fluids by MEKC with direct injection has been done so far with SDS as surfactant in the normal elution mode. The proteins are solubilized by SDS and elute (as a very broad band) after uric acid. With human serum or plasma, several drugs including theophylline[84] (see Figure 8a and b) were shown to elute in an interference-free window in front of uric acid, allowing these substances to be analyzed by direct sample injection. It is also possible to analyze drugs in saliva and, in special cases, also in urine. An introduction to this very interesting field of application of MEKC has been given by Thormann.[85]

Another important area of application of MEKC in drug analysis is direct enantiomer separations. These can be achieved either by employing chiral surfactants or with chiral additives to the separation electrolyte such as cyclodextrins in the presence of achiral micelles.[86]

4.3 Analysis of Food and Beverages

In its present state, MEKC is not a routine method in food analysis. The methods in this field that have been developed so far, however, are very promising and show that MEKC can compete favorably with HPLC. The same advantages as outlined for the analysis of drugs by MEKC (high peak capacity, feasible direct injection,

Figure 9 Analysis of a French red wine after derivatization reaction of the sample with fluorescein isothiocyanate. Analysis by MEKC with LIF detection, $\lambda_{ex} = 488$ nm. Composition of separation electrolyte: 100 mmol L^{-1} boric acid, pH = 9.3 adjusted with NaOH, 20 mmol L^{-1} SDS; $U = 20$ kV. Capillary dimensions: 50 µm inner diameter, 750 mm total length. (1) putrescine, (2) arginine, (3) lysine, (4) histamine, (5) ornithine, (6) histidine, (7) ethanolamine, (8) ethylamine, (9) tyramine, (10) β-phenylethylamine, (11) ammonia, (12) spermidine, (13) spermine, (14) threonine, (15) leucine + isoleucine, (16) proline, (17) phenylalanine + valine, (18) tryptophane, (19) asparagine, (20) tyrosine, (21) serine, (22) alanine, (23) cysteine, (24) taurine, (25) glycine, (26) glutamic acid, (27) aspartic acid, (28) cysteic acid, (b) by-product of derivatization. (Peaks 5 and 17 are not identified in this wine.) (Reprinted from G. Nouadje, N. Simeon, F. Dedieu, M. Nertz, Ph. Puig, F. Couderc, 'Determination of Twenty Eight Biogenic Amines and Amino Acids During Wine Aging by Micellar Electrokinetic Chromatography and Laser-induced Fluorescence Detection', *J. Chromatogr. A*, **765**, 337–343 (1997), Copyright 1997, with permission from Elsevier Science.)

short run times) hold true for the analysis of food and beverages.

Nouadje et al.[87] were able to quantitate 28 biogenic amines and amino acids in red wines by MEKC with laser-induced fluorescence (LIF) detection of the fluorescein thiocarbamate derivatives (see Figure 9). Because of the high peak capacity in MEKC no clean-up steps were required. Bjergegaard et al.[88] developed an MEKC method for the determination of naturally occurring phenolic carboxylic acids (cinnamic and benzoic acid derivatives) in samples prepared directly from dietary fibers and other plant materials. According to Bjergegaard et al., the MEKC method developed is highly effective in comparison with HPLC and GC methods. Szücs et al.[81] determined phospholipids in lecithins by MEKC with photometric detection and concluded that the MEKC method developed was preferable over the International Union of Pure and Applied Chemistry (IUPAC) HPLC method.

4.4 Miscellaneous

As most of the applications of MEKC reported so far are with photometric detection, there is a serious limitation on the applicability of MEKC to trace and ultratrace components in environmental samples. In spite of these limitations, the high peak capacity of MEKC methods can have advantages over conventional techniques in the analysis of very complex samples. Song et al.[89] reviewed the application of MEKC on the analysis of environmental pollutants.

In this context, methods to lower the detection limits are highly desirable. The following approaches are suitable for lowering detection limits in MEKC: on-line concentration (see section 3.7), off-line concentration during sample preparation and improving the sensitivity of detection. The sensitivity of detection can be improved by using detection cells with extended optical pathlength or by application of an alternative detection mode offering a better sensitivity than the conventional detection technique.

With suitable off-line concentration, MEKC can be employed for mono- and mulitresidue analysis of herbicides in tap water at the micrograms per liter level.[90] Van Bruijnsvoort et al.[91] developed a method for the determination of chlorophenols by MEKC with amperometric detection. The detection limits obtained were of the order of $10\,\mu g\,L^{-1}$, one to three orders of magnitude lower than with photometric detection. Luong et al.[92] designed an off-column amperometric cell for the determination of explosives after determination by MEKC. Such a detection system offered a 10-fold detection limit improvement over photometric detection for most of the explosives tested. Penmetsa et al.[93] have shown that with proper precolumn derivatization techniques, LIF detection in combination with MEKC can provide detection limits for herbicides as low as $10\,ng\,L^{-1}$. Thermal lens detection can also offer advantages over photometric detection. Seidel et al.[94] employed MEKC for the separation of nitrophenol pesticides and obtained one to two orderes of magnitude lower detection limits with thermal lens detection than with conventional photometric detection.

5 SEPARATION CARRIER CONCEPT

According to the separation carrier concept developed by Terabe,[7] MEKC is a special form of electrokinetic chromatography (EKC) when micelles are the pseudostationary phase. EKC is a technique that uses electrokinetic phenomena to perform a chromatographic separation. Hence in EKC, generally, charged and neutral solutes can be separated. A prerequisite of a chromatographic separation is a two-phase system, with phases of different migration velocity. This prerequisite can be fulfilled by adding a charged substance, that can incorporate solute molecules, to the separation electrolyte while performing CE. This charged substance, which can incorporate solute molecules, is usable as the 'second phase' (the 'first phase' is the surrounding bulk phase) in EKC. This 'second phase', migrating at a velocity different to that of the 'first phase', has been termed a separation carrier.

Not only surfactant micelles but also microemulsions, polymer ions, polymerized surfactants, dendrimers, resocarenes, charged cyclodextrins and other classes of substances, have been used as separation carriers in EKC. An overview of the different modes of EKC based on a classification of separation carriers was given by Nishi and Terabe[83] and Khaledi.[8] Charged cyclodextrins have found numerous applications in enantiomeric separations.[86] The interest in polymeric phases arises from the fact that they have a stable structure even when surrounded by a phase with a high content of organic solvent. The second advantage of these phases is the nonexistence of dissolved monomers at a concentration corresponding to the CMC of the surfactant. In EKC with an ionic surfactant (MEKC), these dissolved monomers increase considerably the specific conductivity of separation electrolytes.

However, considerations made for micelles as a separation carrier cannot always be directly transferred to the above-mentioned separation carriers. A constraint of Equation (2) and subsequent equations is the assumption that the velocity of the separation carrier is not altered by the incorporation of a solute molecule. At the present stage, it is not clear whether this constraint is fulfilled with all the separation carriers listed above.

Miniaturization is a general trend in analytical chemistry. In the field of separation science, this trend has led to the development of microscale techniques based on high-performance liquid chromatography (HPLC) and electrophoresis. Two such techniques, microscale high-performance liquid chromatography (or micro LC) and capillary electrochromatography (CEC) are the subjects of this article. Micro LC is a general term that encompasses HPLC separations in which the column diameter is less than 1.0 mm. CEC is a hybrid of micro LC and capillary electrophoresis (CE). Relative to the conventional scale technique, micro LC possesses several advantages, namely higher efficiency, often shorter analysis times, reduced solvent consumption and higher mass sensitivity. Micro LC is uniquely suited for analysis of very small sample volumes (e.g. biological cells). It is this type of analysis, a formidable challenge, which has propelled the technique's continued development. CEC most commonly employs conventional HPLC particles packed into fused silica capillary columns. A potential gradient is applied along the capillary; the resulting electro-osmotic flow (EOF) then propels the mobile phase (and analytes) through the column. In CEC, the electric field (generated by a power supply) takes the place of pressure (generated by a pump) in an HPLC separation. One of the most important advantages of CEC relative to micro LC or CE is enhanced resolution. High resolution in CEC arises from the combination of high separation efficiency and selectivity inherent in the technique. CEC, however, is a relatively new technique and its ability to become a ''workhorse'' in the laboratory has not yet been demonstrated.

1 INTRODUCTION

HPLC is one of the most popular and widely applied analytical techniques in use today. Among the many reasons for the technique's popularity are its versatility and wide range of applicability. In its most common form, the modern analytical scale HPLC column has an internal diameter (ID) of 4.6 mm. However, the trend toward miniaturization common throughout analytical chemistry has led to the continued development of smaller diameter columns for HPLC. Today, HPLC in columns having diameters of less than 1.0 mm has evolved into a closely related family of techniques, collectively referred to as *micro LC*. These include open tubular (OT) LC (liquid

chromatography), packed capillary LC and microbore LC. Since the pioneering work of several research groups in the late 1960s and early 1970s, micro LC has grown into an important analytical technique offering several benefits over its conventional scale counterpart. Higher separation efficiencies, decreased analysis time, reduced solvent consumption and increased mass sensitivity are some of the advantages that have propelled the growth of this technique.

Owing to its high resolving power and quantitative capability, microscale LC is ideally suited to analyzing complex, volume-limited samples, for example the contents of individual biological cells. One limitation of micro LC imposed by the small column dimensions, however, is reduced sample loading capacity, which may result in decreased sensitivity relative to conventional LC.

CEC can be viewed as an outgrowth of micro LC. A relatively youthful technique, CEC represents a marriage of packed capillary LC and CE, a separation technique that itself has grown markedly since the early 1980s. In its most common form, CEC employs columns identical to those used in packed capillary LC (i.e. 50–250 μm ID fused silica capillaries packed with reversed-phase, silica-based particles). However, rather than using a pump to drive the mobile phase, bulk flow arises in CEC from electroosmosis, which is induced by an electric field applied across the capillary. For neutral species, the separation mechanism is identical to that in reversed-phase HPLC (i.e. partitioning between the mobile and stationary phases). Charged species, however, will be subject to electrophoresis as well as partitioning, providing a dual separation mechanism that may be employed to increase, or at least alter, selectivity. EOF is intrinsically advantageous for mobile phase propulsion in chromatography owing to its favorable flow dynamics, which result in decreased peak broadening relative to pressure-driven flow. This leads to much higher separation efficiencies in CEC than are obtainable in capillary LC. Higher efficiencies translate into greater resolving power. This combined with the advantages afforded by the small column dimensions (e.g. increased mass sensitivity, short analysis times, low sample volume requirement) make CEC an extremely powerful separation technique.

In contrast to packed capillary LC, the high efficiency of CEC affords high peak capacity, which is useful in analyzing mixtures containing many components. For this reason, CEC is especially suitable for analyzing highly complex samples, such as those involving biological or environmental matrices. As might be expected with a newly developed technique, a disadvantage of CEC is reproducibility.

2 HISTORY

2.1 Evolution of Microscale Liquid Chromatography

The development timeline of micro LC parallels that of ''conventional'' HPLC. Both were challenged and inspired by impressive achievements in the field of gas chromatography (GC). Technological developments in electronics and materials science, coupled with developments in theoretical descriptions of basic chromatographic processes, have driven both techniques toward increasingly better performance.

2.1.1 Semimicro High-performance Liquid Chromatography

The germ of HPLC was realized in 1941, when Martin and Synge published a classic paper in which they described liquid–liquid partition chromatography.[1] They stated that in order to obtain fast separations, small particles and high pressures are required. Their suggestion was realized only in the late 1960s, after the pioneering work of Hamilton et al.[2] in 1960 and Huber et al.[3] in 1967. Most successes of GC such as pellicular and porous packing, temperature programming and especially the use of capillary columns (microbore columns in the present nomenclature) found immediate use in LC. Note that the term microbore as adopted here refers to columns of 1 mm ID. Several names have in the past been used for these columns, such as narrow bore, microbore and small-bore.[4] The various sizes and nomenclature of HPLC columns are presented in the flow chart depicted in Figure 1.

A number of papers published in the late 1960s considered the use of high-pressure LC in the microscale format, primarily with columns having IDs of 1 and 2 mm.[5] Horvath et al.[6] published the first microbore HPLC chromatogram in 1967, which illustrated the use of pellicular packing for the separation of ribonucleoside–monophosphoric acids in about 30 min.

In 1969 Kirkland[7] reiterated the feasibility of the technique by separating urea herbicides in less than 6 min with a 2.0 mm ID column. In 1979 Scott and Kucera[8] showed experimentally that very high theoretical plate numbers (750 000) could be achieved with a microbore column. Five years later, Menet, Gareil and Rosset[9] announced that efficiencies as high as one million plates could be obtained by using a 22 m long microbore column operated at 800 bar inlet pressure.

The ''high speed'' expectation has already been met. Likewise, other advantages of microbore columns such as good resolution, minimal sample volume and low solvent consumption have been realized. In fact, for a while the

Figure 1 Classification of HPLC columns according to ID.

term high-pressure or high-speed LC was synonymous with microbore LC.

In 1970 DeStefano and Beachell[10] used columns with larger diameters (8–11 mm) and achieved efficiencies that at the time were better than those obtained with microcolumns. The improvement is caused by the so-called ''infinite diameter effect'' that occurs when a sample is injected centrally into a wide column. The result is a decrease in band broadening since the ''wall effects'' due to permeability inhomogeneity across the column are diminished. Since then wider bore columns have been the preference and have come to be the convention in HPLC.

2.1.2 *Open Tubular High-performance Liquid Chromatography*

The first LC separation in an OT column was obtained in 1970.[11] A soft glass capillary of 0.23–0.30 mm ID was treated with alkaline solution to generate a silica gel layer and then used to separate dansyl amino acids. Because of the large column diameter, the resolution was poor and the separation required 5 h. Tsuda and Novotny[12] published in 1978 their analysis of band broadening phenomena for unretained species indicating the potential for high-resolution separations with open tubular liquid chromatography (OTLC). In 1978 Ishii applied the results of earlier theoretical studies, which indicated that smaller IDs provide higher efficiencies, and used a microcapillary tube of 60 μm ID. He demonstrated that both physically coated[13] and chemically bonded[14] stationary phases were able to resolve the components of a mixture by LC.

The high efficiency attainable in OTLC was demonstrated by the achievement of 2 800 000 theoretical plates with a 27.5 m long column of 32 μm ID.[15]

For OT capillary columns, large numbers of theoretical plates (>250 000) are not unusual in GC and over the years it has been proven that efficiencies such as this could also be achieved in LC. OT columns have the highest permeability of all column formats, allowing them to produce larger numbers of theoretical plates per unit time and unit pressure drop than packed columns (PCs).

Skill and experience are necessary to obtain OT columns with a uniform stationary phase layer. Covalent bonding of the stationary phase on the walls of the column offered a more uniform and stable coating, which made solvent gradient elution and temperature programming possible. On the other hand, the covalently bonded stationary phase consists of a monomolecular layer having inherently low-analyte capacity; unfortunately OT columns usually require a high-loading capacity to achieve adequate detection limits (DLs).

To achieve maximum efficiency in OTLC requires the use of narrow ID columns, typically 10 μm and below. Peak volumes generated in columns of this size are on the order of 0.1 nL and were incompatible with the detectors available at that time[16] owing to excessive extra-column peak broadening. Unfortunately, this issue limited the use of such columns.

Approaches to increase the sample capacity of the column involved the use of support materials coated on the walls of the capillaries. Supports such as silica gel, porous silica microspheres or organic polymers (polystyrene, polyacrylates)[17] were studied.

The development of fused silica capillary columns in 1979 by Dandeneau and Zerenner[18] revolutionized miniaturized separation techniques. As opposed to the fragile glass columns and surface inhomogeneities of metal columns, the surface of fused silica is smooth, more inert, and the outside polyimide coating makes it flexible and much easier to work with. Before long, fused silica became the material of choice in both the OT and packed capillary format.

The first to investigate LC in fused silica capillaries was Frank Yang, who derivatized columns of different IDs with octadecylsiloxane. The best results were obtained with the 30 μm ID capillary.[19] In the same paper he introduced in situ or on-column detection, which could easily be performed after removing the polyimide coating from a small section of the capillary (2–10 mm). This design effectively eliminated any extra-column volume contribution from the detection cell.

The challenge posed by microbiology on the practical limits of microanalysis drove forward the development of detection systems, such that even smaller ID columns might be used. Their manufacture was not an easy task. In 1988 fused silica capillaries of 2 μm ID were obtained,[20] but the high purity intrinsic to fused silica makes it extremely difficult to increase its surface area by etching in order to enhance column loadability. Therefore, materials used early in the development of LC, such as soda lime glass or borosilicate glass, were etched with acidic and basic solutions to give higher inner surface areas.[21,22] Subsequent chemical bonding of the stationary phases provided the desired selectivity of the OT column.

The requirement of highly specialized instrumentation derived from the limited column loadability narrows the applicability of OTLC.

2.1.3 *Drawn-packed Capillaries*

An interesting alternative solution to the small loadability of OT columns and high-flow resistance parameters of PCs is offered by drawn-packed microcapillary columns, also known as semi-packed microcapillary columns.

These columns were widely used in GC. In 1978 Tsuda and Novotny achieved the first liquid-phase separations in drawn-PCs of 50–200 μm ID, ten times smaller then those currently used in GC.[23]

The manufacturing process consists of packing 1–2 mm ID tubing with sorbent material and subsequently drawing it to the desired diameter using a glass drawing machine. The application of high temperatures during the drawing process results in the impression of some packing material on the walls of the tubing conferring the ''loose'' packing structure specific to this type of column. Unfortunately, such high temperatures preclude the use of derivatized packing materials. Nevertheless, it is possible to prepare various chemically bonded stationary phases in situ, by passing the silane reagent through the capillary.[24] Efficient separations were obtained with a 42 μm ID column of 29.4 m length.[25] Theoretical plate

numbers varied from 400 000 to 880 000 but the analysis required more than 3 h.

2.1.4 Micropacked Capillaries

The low sample capacity of OT columns encouraged scientists to return to the study of PCs for LC. Interestingly, the packed capillary column format actually minimizes the previously described ''wall effects''. For a certain particle diameter, as the walls of the capillary are closer together the overall permeability across the column is more homogeneous.[26,27] This results in a decreased range of flow velocities, smaller pressure drop and more effective dissipation of the frictional heat generated in the column. Thus, in contrast to conventional columns, micropacked capillaries facilitate the use of longer columns, resulting in higher theoretical plate numbers. However, some of the problems encountered with narrow bore columns (such as extra column effects and difficulties in obtaining uniform packing) had to be addressed.

In 1979 Scott and Kucera introduced a low-dead-volume detection cell of 1 μL which significantly improved detection sensitivity.[8] Numerous other geometries were proposed, but on-column detection remains the most popular for fused silica capillaries in spite of the path length limitation it imposes.

In 1969 Knox and Parcher studied the interrelationship between column ID, particle size and plate height.[28] The research, continued by Wilson and McNair[29] for capillary columns, indicated that higher efficiencies can be obtained for Knox–Parcher ratios ρ, defined as the column diameter divided by the diameter of the packing material, of less than five because they generate a more ordered packing structure.

In addition to the general trend toward smaller diameter particles, the design of the packing material itself was continually improved with respect to uniformity in particle and pore sizes. From the small glass spheres coated with a layer of silica gel or microspheres of silica,[7] to the present day material (porous homogeneous covalently bonded microparticles of 2–10 μm), the evolution of packing materials has led to increased column efficiencies. However, conventional (4.6 mm ID) columns packed with the smaller size particles develop an extremely large pressure drop. Capillary columns present one practical solution to this problem. Efficiencies of 100 000 theoretical plates can routinely be attained when columns of 1 m length containing 3 or 5-μm particles are used.[30]

Column packing was extensively studied and methods such as balanced density slurry and vacuum pulled slurry were commonly used.[4] In the first procedure the packing material was mixed with a solvent of similar density (tetrachloromethane), such that the slurry obtained was less susceptible to aggregate formation during packing. High pressures (700–1000 bar) were used to force the slurry into the capillary, the result being a homogeneous, well-packed chromatographic bed. For glass, PTFE (polytetrafluoroethylene) and other tubing materials that could not withstand such high pressures, the packing method proposed by Ishii,[31] which used vacuum to pull the slurry into the capillary, was appropriate. After packing, a compression step was required to compact the bed.

The flexibility of fused silica and availability of polymeric ferrules that permit high-pressure operation greatly facilitated the development of improved packing techniques. Novotny et al. modified the slurry packing method by using higher density slurries, which were sonicated during packing to maintain homogeneity. A less viscous solvent (acetonitrile) was used as both slurry and displacement fluid.[30] The use of acetonitrile also decreased the time required to pack and depressurize the column. It must be stressed that the optimum slurry and/or displacement solvent may vary with packing materials which have different surface chemistries.

Considering the performance of micropacked capillaries coupled with the versatility of the packing materials already available for conventional LC, it is widely considered that the micropacked capillary format of micro LC has the greatest potential for continued development and application.

2.2 Capillary Electrophoresis and Its Influence on Microscale Liquid Chromatography

As early as 1877, Helmholz studied the effect of the application of an electric field across a glass capillary filled with a salt solution.[32] He determined that the wall of the capillary acquired a negative charge, and that while voltage was applied, positively charged particles associated with the wall moved toward the cathode. This nondiscriminatory transport process was termed electroosmosis or electroendosmosis.

The movement of charged particles in solutions under the influence of an electric field, the other electric-field driven transport mechanism, called electrophoresis, was intensively studied by electrochemists. Not until 1937 did electrophoretic migration catch the interest of a separation scientist. Tiselius exploited the differences in electrophoretic mobilities of proteins to separate them, and UV (ultraviolet) photography to detect them.[33] In these studies, it soon became obvious that resistive heating of the solution caused severe band broadening and the appended cooling systems could not effectively eliminate the problem. In spite of this limitation, several separation techniques, including free zone electrophoresis, isotachophoresis, isoelectric focusing, all of which are

based on electrophoretic transport, have become important analytical tools, especially in the fields of biology and biochemistry.

Column miniaturization became fashionable in the early 1960s and with good reason. In 1970 Hjerten[34] introduced surface coating of the walls of small capillaries to minimize electroosmosis, which resulted in essentially pure electrophoretic migration of species. The benefits introduced by column downsizing, such as increased heat dissipation, sensitive real-time detection, applicability to samples in limited amount and ease of automation were notable. The significant increase in efficiency revealed in 1981 by Jorgenson and Lukacs[35] provided a major breakthrough in the field of electrophoresis.

A term was required for the new technique and CE was an obvious choice. The ever-increasing number of practical applications that span from small organic and inorganic molecules, to bio and synthetic polymers, drugs, food additives, and so on, established the name ''high-performance CE''.

Before long, several other variations of CE were developed. Some of the methods that stemmed from CE adopted the electric-field driven migration of the sample and solvents as a bulk transport mechanism. This is the point at which CE, which owed its rapid progress to the ready application of available chromatography advances, began to reward its predecessor.

2.3 Crossroads of Capillary Electrophoresis and Liquid Chromatography: Micellar Electrokinetic Capillary Chromatography and Capillary Electrochromatography

In 1984 Terabe et al. proposed an interesting separation technique which he referred to as micellar electrokinetic capillary chromatography (MEKC).[36] In this technique an anionic surfactant (SDS (sodium dodecyl sulfate) is widely used) is added to the buffer of the CE system at a concentration higher than its critical micelle concentration, such that it forms transient micelles. During a run the neutral components of the sample move towards the cathode carried by the EOF. Given the negative charge of the micelles, the direction of electrophoretic migration is toward the anode. However, in uncoated capillaries the magnitude of the EOF vector is usually larger than the electrophoretic component of the micelle. Therefore, the micelles migrate toward the cathode, although at a lower speed than the bulk solution. If an analyte partitions into the micelle, it moves during the period of association at the micelle velocity. Different affinities for the micelles, hence different partition coefficients into the ''pseudostationary phase'' allow for the separation to occur. Thus, MEKC is a chromatographic technique because the separation mechanism is based on distribution equilibria.

Although the invention of MEKC greatly widened the applicability of CE, it did not broaden the technique to the point of universal utility. Analytes that partition into the micelles are sparingly soluble in water and only small amounts of organic modifiers could be added to enhance solubility without perturbing the formation of micelles. Techniques that allow the use of high concentrations of organic solvents would perhaps be more versatile.

In 1974 Pretorius et al. studied electroosmosis in packed glass tubes and observed that irregularity in the packed bed did not affect the chromatographic performance.[37] High efficiencies were obtained for unretained species, indicating the potential of the technique. In 1981, Jorgenson and Lukacs replaced the high-pressure pump of micro LC with EOF in 170-μm ID, 68-cm long capillaries packed with 10-μm reversed-phase particles.[35] The column generated over 20 000 theoretical plates corresponding to reduced plate heights of 1.9 and 2.5. At the time, the typical optimum reduced plate height for PCs was 2.5, so these values demonstrate the potential for ultrahigh efficiencies for electro-driven separation techniques. This application of electroosmosis for bulk transport in micro LC would later be called CEC.

In 1988, Knox described the theory of CEC operation,[38] but the method was not widely researched before a new paper was published in 1991.[39] There, Knox employed both slurry packed capillaries and drawn-packed capillaries in a comprehensive study of the effect of particle size on EOF velocity. He found that particle size had essentially no effect on velocity and electrolyte concentration as low as 0.002 M resulted in a relatively fast analysis with high efficiency. An impressive 500 000 plates m^{-1} and reduced plate heights of 1.3 were obtained for the slurry PC.

3 THEORY

3.1 Efficiency and Its Effect on Resolution in Chromatography

In LC, separation is achieved by the differential migration of solutes through the column, which arises due to the solutes' partitioning behavior between the stationary phase and flowing solvent (mobile phase). The quantitative measure of the separation of any two components is resolution (R_s). Resolution is an important chromatographic feature of merit because it is a measure of the ability of the system to distinguish between closely spaced components in a separation. The goal in chromatography is to obtain adequate resolution of the components of interest in a minimum amount of time.

Separations in which many components must be resolved are often the most challenging. This is typically the case when the species to be analyzed are present in a complex matrix. To obtain adequate separations with these samples generally requires high resolution. To meet these challenges, there is an ever-present need to seek ways in which chromatographic resolution can be maximized while at the same time minimizing analysis time.

The master resolution equation expresses resolution as a function of three basic chromatographic parameters: capacity factor, selectivity and efficiency

$$R_s = \frac{1}{4}\left(\frac{k'}{1+k'}\right)\left(\frac{\alpha-1}{\alpha}\right)\sqrt{N} \qquad (1)$$

The first term in Equation (1) is capacity factor (k') dependent. The capacity factor for a given solute is a measure of its affinity for the stationary phase (it is proportional to the solute's thermodynamic partition ratio). If all other variables are held constant, a solute with a lower value of k' will migrate through the column faster (i.e. have a shorter retention time) than a solute with a greater k'.

The second term in the equation is selectivity, or separation factor, (α) dependent. Selectivity, which is measured for a pair of peaks, is simply the ratio of their capacity factors. Selectivity values are by definition greater than or equal to one and indicate differences in the affinities of analytes for the stationary phase. Capacity factor and selectivity are dependent upon the thermodynamics of the solute–stationary phase interaction.

The third term in the master resolution equation is efficiency (N) dependent. Efficiency is related to the narrowness of the chromatographic peak and is expressed as the number of theoretical plates. Unlike capacity factor and selectivity, efficiency is chiefly affected by physical, rather than chemical processes that occur as the solute passes through the column. These processes include kinetic phenomena such as molecular diffusion, slow mass transfer and others that result in broadening of peaks as they migrate through the column. Efficiency is quantified by Equation (2):

$$N = \frac{t_r^2}{\sigma^2} \cong 16\left(\frac{t_r}{W_b}\right)^2 \qquad (2)$$

where t_r is the retention time of the peak, σ^2 is the peak variance (the square of the standard deviation σ) in units of time and W_b is the peak width at baseline in time units.

From Equations (1) and (2) it is evident that peak broadening degrades resolution. It is desirable, then, to minimize peak broadening by understanding and minimizing (as much as it is possible) its causes.

A more useful parameter with which to assess chromatographic peak dispersion is the height equivalent to a theoretical plate or plate height (H), which is given by Equation (3):

$$H = \frac{\sigma^2}{L} \equiv \frac{L}{N} \qquad (3)$$

where σ^2 is the peak variance and L is the column length. Plate height is a measure of peak broadening per unit column length. Assuming Gaussian peaks, which under most conditions is a reasonably valid assumption, plate height may be viewed as the length of column that "contains" one theoretical plate (Equation 3).

Greater values of H correspond to broader peaks. Because plate height is a measure of peak broadening per unit length of column, it is often a more useful feature of merit than N in that it allows direct comparisons between columns of different lengths. In PC chromatography, plate height is often expressed in its reduced form, h, ($h = H/d_p$) in which it is normalized to the packing particle diameter (d_p).

Let us now examine the phenomena that contribute to H. According to chromatographic rate theory, peak broadening arises from various kinetic factors that occur as the solute zone passes through the column. The following well-known relationship, which derives from chromatographic rate theory, expresses plate height as the sum of individual contributions, Equation (4):

$$H = A + \frac{B}{\mu} + C_s\mu + C_m\mu \qquad (4)$$

In this general form of the equation, the A term represents the plate height contribution due to eddy diffusion and the B term represents axial molecular diffusion. The contributions of slow solute mass transfer in the stationary and mobile phases are contained in the C_s and C_m terms, respectively. Mobile phase linear velocity is given by μ. It is common in chromatography to depict the dependence of H on μ graphically in the form of a Van Deemter plot.

The eddy diffusion or A term in Equation (5) arises primarily from the multiple pathways in a packed bed through which solute molecules can flow. A molecule traveling a less tortuous path will travel faster relative to the average condition. Conversely, a molecule traveling in a more difficult path will fall behind with respect to the average. The resultant chromatographic peak, a distribution of arrival times about a mean value (the peak apex), becomes broadened. It has been shown that the magnitude of the A term is proportional to the diameter of the packing particle:

$$A \propto d_p \qquad (5)$$

Axial, or longitudinal molecular diffusion, represented by the B term, is the plate height contribution caused

by diffusion of solute molecules along the column axis. The B coefficient is proportional to the solute's diffusion coefficient in the mobile phase. The slower the velocity of the solute zone through the column, the more time is available for diffusion to occur, thus there is an inverse relationship between mobile phase velocity and the magnitude of this contribution. In liquids, the diffusion coefficients of solutes are small (typically on the order of $10^{-5}\,cm^2\,s^{-1}$). For this reason, the effect of axial diffusion on plate height is minimal under typical operating conditions.

A finite amount of time is required for solute molecules to enter and leave the stationary phase. The rate of this exchange has an inverse effect on plate height (slower exchange results in broader peaks). The C_s term of the plate height equation represents this contribution to plate height. As might be expected, the value of C_s is related to the thickness of the stationary phase layer on the particle surface. In modern LC, the stationary phase film is typically formed as a monolayer on the particle surface. Because of this, slow mass transfer in the stationary phase is usually a minor contributor to plate height.

The contribution to plate height of slow mass transfer kinetics in the mobile phase is included in the C_m term. In even the most well packed LC column, point to point differences in mobile phase velocity exist. For example, velocity differences arise from the intrinsic nature of laminar (pressure-driven) flow. Consider for instance that in any microscopic flow channel within the packed bed (e.g. in the packing interstices), the flow velocity is at some maximum value at the channel center and zero at the particle surface owing to friction. Between these extremes, flow velocity varies as a function of distance from the center. Molecules near the center of the channel will outdistance those near the particle surface, broadening the zone. Diffusion of solute molecules into and out of the various velocity regimes serves to counteract the zone broadening effect. However, as discussed above, diffusion coefficients in liquids are small and so this velocity nonhomogeneity effect contributes to plate height. Slow solute diffusion in the mobile phase results in additional zone broadening effects when porous packings are employed. Stagnant mobile phase mass transfer involves pools of nonflowing mobile phase deep inside the pores of the packing material. Solute molecules that diffuse into these pools fall behind with respect to the average and the peak broadens. Because diffusion is the sole mechanism by which solute molecules enter and leave the pools, the slow diffusion rates of solutes in liquids exacerbate zone broadening due to this process.

Not surprisingly, the C_m term scales in inverse proportion to the solute's diffusion coefficient in the mobile phase (D_m). The proportionality in Equation (6) shows the dependence of C_m on particle size and the diffusion coefficient:

$$C_m \propto \frac{d_p^2}{D_m} \tag{6}$$

3.2 Advantages of Column Miniaturization

The ongoing evolution of HPLC has led to the development of ever-smaller column diameters (<1.0 mm) since the mid 1980s. The impetus for this miniaturization has been the numerous advantages afforded by miniaturized columns. These advantages include:

- improved column permeability, resulting in enhanced efficiency
- decreased solvent consumption
- increased mass sensitivity
- more efficient heat transfer
- less packing material required
- more facile interfacing with mass spectrometry (MS).

Let us now examine each of these advantages in greater detail.

3.2.1 Column Permeability

The permeability of a chromatographic column is a measure of its resistance to flow and is related to the dimensionless flow resistance parameter ϕ, Equation (7):

$$\phi = \frac{\Delta P d_p^2}{\mu L \eta} \tag{7}$$

where ΔP is the pressure drop, d_p is the particle diameter, L is the column length, η is the mobile phase viscosity and μ is the mobile phase linear velocity. Rearrangement of Equation (7) shows a direct proportionality between ΔP and ϕ. With a fixed set of operational conditions (i.e. fixed d_p, L and η), the pressure drop required to obtain a particular linear velocity is dependent upon ϕ. This is relevant in LC because there is an upper limit to the pressure attainable by conventional instrumentation (usually no higher than 400 bar). This in turn places limits on L and d_p, which affect efficiency, and μ, which affects analysis time. Within these limits, optimizing the separation usually involves a compromise between efficiency and speed.

A useful parameter in assessing the performance characteristics of LC columns that incorporates pressure drop and analysis time is separation impedance ($E^\dagger$). This dimensionless parameter introduced by Bristow and Knox[40] is a measure of column efficiency per unit time and per unit pressure drop, and is defined by Equation (8):

$$E^\dagger = \left(\frac{t_0}{N}\right)\left(\frac{\Delta P}{N}\right)\left(\frac{1}{\eta}\right) = \left(\frac{H}{d_p}\right)^2 \phi \tag{8}$$

Table 1 Values of h, ϕ and $E^{\dagger}$ for various column diameters

Column type	h_{min}	ϕ	$E^{\dagger}$
Narrow bore and conventional PCs ($d_c/d_p > 10$)	2	500–1000	2000–4000
Packed capillary columns ($d_c/d_p \approx 2.5$)	2	150	600
OT columns	0.8	32	20

Adapted from Knox.[41]
h = reduced plate height, ϕ = flow resistance parameter, $E^{\dagger}$ = separation impedance.

Table 2 Comparison of volumetric flow rates for various column diameters operated at fixed linear velocity (approximately three times optimum velocity)

Column diameter (mm)	Volumetric flow rate ($\mu L\,min^{-1}$)
4.60	1400
1.00	66
0.530	19
0.100	0.66
0.050	0.16

Assumed conditions: $\varepsilon_{tot} = 0.7$; $\mu = 2.0\,mm\,s^{-1}$.

where t_0 is the elution time of an unretained solute; other variables are defined previously. Lower values of $E^{\dagger}$ correspond to better column performance. Values of $E^{\dagger}$ and ϕ for various column diameters are shown in Table 1. The lower $E^{\dagger}$ values of miniaturized columns mean that these columns can yield more theoretical plates in less time and with a lower pressure drop relative to conventional bores.

The enhanced permeability of miniaturized columns allows for further increases in efficiency by making possible the use of smaller packing particles and/or longer columns. Recall from Equations (4–6) that plate height is related to particle size through the A and C_m terms of the plate height equation and efficiency is proportional to column length (Equation 3). In spite of this, conventional columns are constrained by excessive pressure drop, which limits usable lengths and particle sizes. Most 4.6-mm columns are 150–250 mm long and employ 5 µm particles. Alternatively, the use of smaller particles can result in reduced analysis times because when particle size is reduced, a given plate number is achievable with a shorter length of column.

3.2.2 Solvent Consumption

Decreasing column diameter results in a substantial reduction in the volumetric flow rate required for a given linear velocity. Volumetric flow rate (F) through a PC is given by Equation (9):

$$F = \frac{\pi d_c^2 \varepsilon_{tot}\,\mu}{4} \tag{9}$$

where d_c is the column diameter and ε_{tot} is the total column porosity. The dependence of F on the square of column diameter translates into significant reductions in solvent consumption on miniaturization. Table 2 compares volumetric flow rates for various column diameters. For example, downsizing to a 1.0-mm ID from a conventional 4.6 mm will reduce solvent consumption over 20-fold. Decreased solvent consumption is economical (reduced purchase and disposal costs) as well as environmentally responsible.

3.2.3 Mass Sensitivity

Chromatographic separations are intrinsically processes of dilution: an initial sample plug of concentration C is diluted in the mobile phase and reaches the detector as concentration C' (where $C' < C$). Because the majority of LC detectors are concentration-based, a reduction in sensitivity results. To understand why this process is ameliorated upon column miniaturization, we will define peak volume (V_p). Assuming a Gaussian peak, Equation (10):

$$V_p = FW_b = \left(\frac{\mu \varepsilon_{tot} \pi d_c^2}{4}\right) W_b \tag{10}$$

where W_b is the peak width at baseline in units of time. V_p is simply the volume over which the peak elutes. According to Equation (10), peak volumes are proportional to the square of column diameter; thus values of V_p for microcolumns are substantially smaller than for conventional 4.6-mm columns.

The concentration of solute at the peak maximum is inversely proportional to V_p.[4] Qualitatively, this relationship can be envisioned as follows. A given mass of solute is diluted in a volume V_p yielding a concentration C. If the same mass is diluted in a smaller volume V_p', the resulting concentration C' will exceed C in proportion to the volume difference. As indicated in Table 3, for a fixed mass of solute injected, column miniaturization can result in substantial increases in sensitivity with concentration-based detectors (e.g. UV, fluorescence).

3.2.4 Other Advantages

Decreased cross-sectional area allows for more efficient heat transfer to and from the column interior. Relative to conventional bore columns, miniaturized columns are capable of more rapid equilibration at different temperatures, which makes possible the use of temperature

Table 3 Typical peak volumes and relative sensitivity of various column diameters

Column diameter (mm)	Peak volume V_p (μL)	Relative sensitivity[a]
4.60	350	1.0
1.00	17	20
0.530	4.8	75
0.100	0.17	2000
0.050	0.040	8500

Assumed conditions: $L = 250\,\text{mm}$; $k' = 2$; $N = 10\,000$; $\mu = 2.0\,\text{mm s}^{-1}$; $\varepsilon_{tot} = 0.7$.
[a] This calculation is based on a fixed mass of solute injected and a concentration-based detector.

programming as in capillary GC. In addition, these columns can more effectively dissipate heat generated by the pressure drop, minimizing temperature gradients that can cause peak broadening. Smaller volume columns require less packing material, which is beneficial if costly ''exotic'' materials are used. This is also the case for mobile phases.

The low volumetric flow rates of miniaturized columns simplify interfacing to MS. Columns may be interfaced directly using thermospray, electrospray and other means, obviating the need for flow splitting, which reduces sensitivity.

3.3 Extra-column Effects

Not all peak broadening occurs within the chromatographic column. In addition to the phenomena accounted for in the plate height equation (Equation 5), which occur as the solute band passes through the column, the final peak width is affected by so-called extra-column effects. These include contributions from the sample injector, the injection volume, connecting tubing, detector cell volume and the detector time constant. Well-designed chromatographs are constructed such that extra-column effects comprise a small fraction ($\leq$10%) of the final peak width. One disadvantage of column miniaturization is that the system becomes more susceptible to extra-column effects as column diameter decreases.

Peak volume (V_p) was defined in Equation (10) as the peak width at baseline in units of volume. For Gaussian peaks, the final peak volume observed at the detector V_{obs} can be expressed in terms of the in-column V_p and extra-column V_{ec} contributions, Equation (11):[42]

$$(V_{obs})^2 = (V_p)^2 + (V_{ec})^2 \tag{11}$$

Dividing through by V_p^2 gives the relative increase in V_{obs} from extra-column effects, Equation (12):

$$\left(\frac{V_{obs}}{V_p}\right)^2 = 1 + \left(\frac{V_{ec}}{V_p}\right)^2 \tag{12}$$

According to this equation, if the extra-column contribution to the final peak volume, V_{obs}, is to be limited to 10%, then the extra-column volume must not exceed 46% of the column peak volume. This poses less of a problem with the relatively large peak volumes encountered with conventional bore columns. However, because peak volumes are proportional to the square of column diameter, to maintain the same fraction (10%) of extra-column broadening in micro LC requires much more stringent control of extra-column volumes. In such cases, extra-column volumes must be significantly reduced in order to minimize the contribution to the final peak volume. As a consequence, conventional HPLC instrumentation (i.e. injector, tubing and detector) must be modified in order to accommodate smaller diameter columns, which is a disadvantage of micro LC. Table 4 lists maximum allowable values for injection volume, connecting tubing length and detector cell volume for various column diameters.

In addition to the dilution and mixing that occurs within extra-column volumes, a contribution to band broadening may arise from the detection electronics. The speed with which the detector responds to a change in

Table 4 Maximum allowable extra-column volumes for various column diameters

Column diameter (mm)	Peak volume (μL)	Injection volume[a] (μL)	Tubing length[b] (cm)	Tubing length[c] (cm)	Cell volume[d] (μL)
4.60	350	40	31	N/A	15
1.00	17	1.9	0.071	940	0.73
0.530	4.8	0.54	0.0040	270	0.17
0.100	0.17	0.019	N/A	9.4	–[e]
0.050	0.040	0.0045	N/A	2.2	–[e]

Assumed conditions: $\varepsilon_{tot} = 0.7$; $\mu = 2.0\,\text{mm s}^{-1}$; $N = 10\,000$; $L = 250\,\text{mm}$; $k' = 2$; $D_m = 10^{-5}\,\text{cm}^2\,\text{s}^{-1}$.
[a] Allows 5% peak broadening.
[b] Allows 3% peak broadening, connective tubing diameter = 250 μm.
[c] Allows 3% peak broadening, connective tubing diameter = 50 μm.
[d] Allows 3% peak broadening.
[e] Assumes on-column detection with a negligible extra-column volume contribution.

solute concentration is affected by its time constant, τ. The time constant, which typically can be adjusted within a range of values, is useful as a filter for high-frequency noise in the chromatogram. Longer time constants slow the detector response providing enhanced signal filtering. Problems arise when the chromatographic peaks are very narrow, as in high efficiency separations. In these cases, slow detector response (long time constants) will result in additional peak broadening. It can be shown[43] that the maximum allowable time constant for a given fraction of peak broadening is proportional to $1/\sqrt{N}$. Thus, detectors employed in high efficiency separations require more rapid detection electronics.

3.4 Flow Profile and Efficiency: Advantages of Electro-osmotic Flow

EOF originates near the fused-silica capillary wall (or packing particle surface) owing to a charge imbalance that exists at the surface–liquid interface. The surfaces of fused-silica tubing and silica-based packing materials bear a net negative charge owing to the presence of ionized silanol moieties ($Si-O^-$). When exposed to a solution containing oppositely charged ions (e.g. the mobile phase), the surface will attract counterions to preserve electroneutrality. The attracted counterions form a two-part layer at the surface, known as an electrical double layer. The Stern layer consists of immobile counterions tightly affixed to the surface. A second layer, the Gouy or diffuse layer, extends some distance from the surface. The counterions present in this diffuse region are mobile and freely exchange with counterions in the bulk solution. The electrical double layer is depicted in Figure 2. Upon application of an electric field, counterions in the diffuse region begin to migrate toward the electrode of opposite polarity (generally the cathode). Because these migrating ions are solvated and because of frictional forces, the bulk solution is dragged toward the respective electrode. Electroosmosis is particularly advantageous as a driving force for mobile phase flow in chromatography because it generates considerably less peak broadening relative to pressure-driven flow. This is mainly because of the more uniform velocity profile of EOF. In fact, the potential to combine the selectivity of HPLC with the favorable flow dynamics of electroosmosis has been a driving force in the development of CEC. There are three main advantages of EOF over pressure-driven flow for mobile phase propulsion in chromatography: (1) EOF flow velocity is radially uniform (across flow channel), (2) EOF flow velocity is independent of channel diameter, and (3) EOF requires no pressure drop. Let us explore each of these points in greater detail.

Consider a capillary tube of radius r_c. In pressure-driven (or laminar) flow, the flow velocity at any radial

Figure 2 Schematic representation of the electrical double layer near the surface of fused-silica capillary tubing.

point in the tube $u(r)$ is a function of distance from the center as given by the Hagen–Poiseuille Equation (13):

$$u(r) = \frac{\Delta P}{4\eta L}(r_c^2 - r) \tag{13}$$

where r is the distance from the tube center. The resultant flow velocity profile is parabolic in shape. There exists a distribution of velocities over the tube cross-section. Recall from the discussion of the mobile phase mass transfer contribution to plate height (section 3.1), that such velocity inhomogeneity leads to an increase in plate height. More specifically, this zone-broadening phenomenon is known as the transchannel effect.[44]

Consider now EOF through the same capillary tube. EOF velocity (v_{eo}) at any radial point in the tube is given by Equation (14):

$$v_{eo} = \frac{\varepsilon\zeta E}{4\pi\eta}\left(1 - \frac{I_0(\kappa_d a)}{I_0(\kappa_d r)}\right. \tag{14}$$

where ε is the permittivity of mobile phase, ζ is the zeta potential, E is the electric field strength, η is the mobile phase viscosity, κ_d is the reciprocal of the thickness of the double layer, a is the distance from the center of the tube and I_0 is a zero-order Bessel function of the first kind.

Typically, the double layer thickness is quite small (on the order of 1 nm) and the term in parentheses reduces to one, yielding the following expression, Equation (15):

$$\langle v_{eo}\rangle = -\frac{\varepsilon\zeta E}{4\pi\eta} \tag{15}$$

where $\langle v_{eo}\rangle$ indicates the average flow velocity in the tube. Equation (15), which is valid in the absence of double-layer overlap, shows that EOF velocity is independent of radial position in the flow channel. Thus, the flow profile is flat over most of the capillary cross-section. Figure 3

Figure 3 Radial flow velocity profiles of pressure and electrically driven flow through open tubes. Arrows depict velocity vectors.

compares the radial profiles of pressure and electrically driven flow. This uniformity in flow velocity minimizes transchannel zone broadening, resulting in a lower C_m term in the plate height equation.

In packed chromatographic columns, there invariably exist local differences in packing density which give rise to interstitial flow channels of varying diameter. With pressure-driven flow, the squared dependence of velocity on channel diameter (Equation 13) gives rise to a distribution of velocities in these channels. As in the transchannel effect discussed previously, point to point differences in flow velocity contribute to zone broadening. The plate height increment due to this phenomenon is part of the eddy diffusion (A) term of the plate height equation.

In contrast, EOF velocity, which is essentially independent of channel diameter, results in a much more uniform distribution of velocities in spite of differences in local packing density (depicted in Figure 4). We can expect the improved velocity distribution of electrically driven flow to result in a lower A term in the plate height equation.

The third advantage of EOF is that no pressure drop is required. This is important from the standpoint of efficiency because it permits the use of smaller diameter particles. Plate height, as discussed in section 3.1, is strongly dependent upon particle diameter and decreases with a decrease in d_p. In HPLC this advantage is offset by the inverse square dependence of pressure drop on d_p (Equation 7). The maximum pressure attainable by most

Figure 4 Schematic depicting EOF through a packed chromatographic column. Arrows represent velocity vectors, which are uniform through channels of varying diameter.

Table 5 Comparison of achievable efficiency and peak capacity in micro LC and CEC with various particle sizes

Particle diameter (μm)	CEC		micro LC	
	Plates per column	Peak capacity	Plates per column	Peak capacity
5	59 000	147	40 000	121
3	98 000	189	47 000[a]	130
1.5	200 000	269	24 000[b]	94

Assumed conditions: linear velocity = 1.0 mm s^{-1}; column length = 50 cm; high-pressure limit (micro LC) = 400 bar; $k'_{max} = 10$; Reduced plate heights: $h_{cec} = 1.7$, $h_{\mu-LC} = 2.5$.
[a] Column length limited to 35 cm owing to high-pressure limit.
[b] Column length limited to 9 cm owing to high-pressure limit.

commercial LC pumps is about 400 bar, which in most cases limits particle diameter to not less than 3 μm. With no such limit, CEC separations regularly employ 1.5-μm particles and the potential exists to employ much smaller particles.[45]

Reduced plate height values obtained for the same columns under electrically and pressure-driven conditions have been shown to be consistently lower under the former,[39] a direct result of the improved flow dynamics of EOF. Greater efficiency, combined with the absence of pressure drop gives CEC the potential to generate total column plate numbers that are substantially higher than micro HPLC.

An important feature of merit for a chromatographic technique is peak capacity, which is defined as the number of peaks with unit resolution that can be contained in the column. Peak capacity, then, is a measure of the applicability of a separation technique to highly complex samples (i.e. those containing large numbers of peaks). In comparison to capillary GC, peak capacity in HPLC is limited by the relatively low efficiency of the technique. In contrast, the high separation efficiency of CEC provides increased peak capacity. Table 5 compares typical column efficiency and peak capacity values achievable in CEC and capillary HPLC.

4 INSTRUMENTATION

Although capillary columns offer numerous advantages, their full exploitation is limited by the technological ability to miniaturize the instrumentation properly.

4.1 Columns for Microscale Liquid Phase Separations

4.1.1 Column Performance

All types of packing material offered for conventional HPLC can be used in micro LC. However, submicron size packing materials have been synthesized to increase column performances, considering the fact that pressure drop is no longer a limitation in the micro HPLC format. Moreover, the CEC stationary phase must be able to sustain EOF; thus charged groups need to be incorporated in the packing particles in the case of PCs, or on the capillary surface in OT columns.

Undoubtedly, OT columns offer the highest separation efficiency and highest permeability. Numerous papers have indicated that 1 million plates can routinely be obtained[17] with reduced plate heights on the order of 1.

In micro LC, drawn-packed capillary columns provide efficiencies of 100 000 plates m^{-1} if very long columns are prepared and if long analysis times are acceptable. Such performances are comparable to the packed capillaries, so both types of columns were considered in micro HPLC.

However, in CEC mode the drawn-packed capillaries showed efficiencies of 100 000 plates m^{-1}, considerably lower than the 500 000 plates m^{-1} obtained with the packed capillaries.[39] Since the manufacturing of drawn-packed capillaries is much more elaborate and the columns are fragile compared to the fused-silica ones, these columns are no longer used for CEC.

Packed capillary columns of 100–300-μm ID routinely offer 100 000 plates per meter in micro LC with 5-μm particle diameters (C_{18}). The reduced plate heights obtained vary between 2.2 and 3, close to the theoretical limit of two accepted for pressure-driven liquid chromatographic systems.[40] Kennedy and Jorgenson[27] demonstrated that columns of ID smaller than 50 μm may yield even smaller reduced plate heights, $h_{min} = 1.5–1.8$. For these columns the separation impedance ranges from 1300 to 2500; thus longer columns can be used and extremely high separation efficiencies are possible.[27,46]

Jorgenson explained this effect in a later paper,[47] in which he indicated that microcolumns and conventional columns contain two regions of packing, which are differentiated by their permeability. In the core of the column, the more tightly packed region comprises the first region, while the second region, loosely packed, is near the walls of the capillary.

In CEC two notable benefits are provided by EOF: the flat profile, which as mentioned earlier provides increased efficiency per unit length, and the potential for use of very long columns, which derives from the absence of flow resistance as encountered with conventional pumps. Thus, in CEC reduced plate heights of 1.5 are easily obtainable and total plate counts in excess of 150 000 are possible.

Pressure-driven flow is at present more reproducible than EOF. Column-to-column irreproducibility (RSD (relative standard deviation) larger than 4%) is more significant than run-to-run irreproducibility (RSD currently 1–2%). Some analysts consider that this may be caused by column-to-column irreproducibility in packing, frit fabrication and column surface chemistry.

4.1.2 Column Preparation

Columns in both the OT and packed capillary format are commercially available from companies such as LC packings, Unimicro, Micro-Tech, Keystone and others. However, in most research laboratories the columns are home built using fused-silica tubing available from Polymicro Technologies (Phoenix, AZ, USA) and others using procedures similar to those outlined below.

In OT columns the stationary phases are attached to the walls of the capillary by covalent bonding or by polymer coating. Both procedures require an etching step which activates the silanol groups of the fused silica surface, such that most of them can participate in stationary phase bonding and will not interfere with the retention mechanism. The chemical bond in the first column type, commonly known as a monolayer column, is formed between anchoring groups and molecules that will serve as, and determine, the selectivity of the stationary phase.

Polymer coatings are often preferred to the monomolecular phases because the thick layer of stationary phase ensures an increased sample capacity and solute retention. The in situ procedure comprises the introduction into the column of a mixture containing the functional monomer (often acrylate), initiator, cross-linker and solvent. During the polymerization process,

which can be initiated thermally or via UV radiation, the solvent is evaporated and the oligomers are left immobilized on the surface.[48] If suitable anchoring groups are attached to the surface before introducing the polymerization mixture, the polymeric network is covalently bonded onto the surface and the column is more stable. For polyacrylate phases, used in both micro LC[17] and CEC,[49] the selectivity factors vary from capillary to capillary within 1 and 2% RSD. Prior to use, the columns are flushed with the appropriate mobile phase.

The quality and lifetime of PCs is directly dependent on the homogeneity of the packed bed. The method most often used for preparing a PC is the slurry packing technique. Dry packing methods, which claim shorter packing times and similar column performances, have also been used for both polar and nonpolar stationary phases.[50]

In a typical slurry packing procedure, the packing material and about 1 mL of solvent (selected for compatibility with the packing material; for reversed-phase, acetonitrile and water often yield the best results) are thoroughly mixed and sonicated, then transferred to a stainless steel reservoir. The reservoir contains a metal frit and is connected on one side to a high-pressure pump that is filled with a displacement solvent. The capillary to be packed, the outlet side of which contains a retaining frit (made of silica, Teflon™, glass wool or metal) is fitted to the opposite side of the reservoir. In order to ensure the homogeneity of the slurry, a tiny magnetic stir bar placed into the reservoir can be used for mixing. Also the reservoir can be placed in an ultrasonic bath, and sonicated during packing. These features are essential to minimize particle aggregation and settling out of the slurry during packing. Pressure is applied and increased gradually up to about 250 bar. When the column has been packed to the desired length, the system is depressurized and the column can be flushed and conditioned with the mobile phase that is to be used for the analysis.

Alternative packing procedures use different means to force the packing material from the slurry reservoir into the capillary. During electrokinetic packing, a potential ramp (2–30 kV) is applied across the capillary and the slurry reservoir such that the charged particles electromigrate into the column.[51] The centripetal-based packing technique uses the centripetal force created by spinning a rotary reservoir onto which numerous capillaries are mounted.[52] Both techniques are suitable for mass production of packed capillaries and have been shown to produce columns offering performance characteristics equal to columns made using more conventional means.

4.1.2.1 The ''Frit Issue'' Before mounting the capillary in the slurry reservoir, the outlet end must be fitted with a porous ''plug'', a frit, which will allow the solvent to pass through while the particles stack to form a packed bed. Thus, frits must be able to withstand the high pressures used during the packing procedure. In micro LC, glass wool, metal and silicate frits are used. For CEC, EOF should preferably be supported by the frit, so silicate frits are typically used. They are easier to make[53] and can provide porosities very similar to those of packed beds. However, the porosity and surface structure of each of these frits is often sufficiently different from the packed bed to result in peak broadening in micro LC and CEC and gas bubble formation in CEC. Also, instability of the current and baseline signals might occur. Moreover, the columns used for CEC designed for on-column detection must have an additional frit at the column outlet, to keep the bed in place during use. These frits can be obtained by packing porous silica particles and heating the outlet area with a highly focused source of heat such as a Ni–Cr coil or a fiber optic fusion splicer. This will partially adhere the silica spheres together to form a frit; the side effect of applying the heat is the total combustion of the polyimide coating, which renders the column extremely fragile. Various compositions for silicate frit preparations have been tried,[53] but none seems to solve the problem completely.

4.1.3 Perspectives

Recent advances in column fabrication include the development of nanosized particles, refinement of chiral selectivity of stationary phases, as well as refinements in the design and fabrication of packing materials specific for CEC separations.

Another trend considers the need to address the frit issue and the best answer seems to be the fritless column. New column designs involve a continuous highly cross-linked porous matrix that can incorporate selective sites, as in the case of ''monolithic'' columns, or can surround the packing material and hold it in place during the operation of ''entrapped'' columns.

Numerous papers published recently have studied the synthesis and performance of monolithic columns.[54–56] The in situ polymerization of an organic or silicate-based monomer within a capillary column acting as a mold produces a continuous rod of rigid highly porous polymer. For CEC the cross-linked polymer is often provided with charged groups (e.g. sulfonic acid groups) able to sustain the EOF. The main advantages offered by silicate matrices over the synthetic organic polymers include resistance to swelling, stability over time and readily available silanol groups for operating in the CEC mode. On the other hand the synthetic polymers offer a wide variety of functionalities and the possibility to operate at a wider range of pH.

The silicate-entrapped columns are made by trapping the packing particles in a network of silica. Therefore,

aside from the robustness afforded the column, the silicate entrapment provides ionizable silanol groups, which result in an increase in the flow velocity and in radial homogeneity of the electric field. Faster separations and modestly increased efficiencies per unit time can be obtained.[57]

4.2 System Components: Microscale Liquid Chromatography

4.2.1 Pumps

The overall accuracy and precision of any HPLC system is strongly dependent on the ability of the solvent delivery system to deliver stable flow rates. The very small volumes (microliters and nanoliters per minute) required by miniaturized columns place an even more stringent demand on micro LC pumping system. Reciprocating piston pumps, which are the standard in conventional HPLC, lack reproducibility at flow rates below about $0.1\,\text{mL}\,\text{min}^{-1}$. For this reason, these pumps are rarely used in micro LC without a flow splitting device.

The majority of micro LC applications employ syringe pumps. This type of pump, a schematic of which is shown in Figure 5, consists of syringe of fixed volume driven by a stepper motor. Syringe pumps, such as those available from Isco (Lincoln, NE, USA) and Carlo Erba (Italy) are capable of delivering precisely metered flow rates, typically within the range of $0.1–1000\,\mu\text{L}\,\text{min}^{-1}$. Advantages over reciprocating piston pumps include better reproducibility at low flow rates and pulse-free operation. The main disadvantage of the syringe pump, a limited volume of solvent, is less problematic with the very low flow rates encountered with micro-columns.

4.2.2 Injectors

In general, the sample injection system in micro LC must be capable of introducing very small volumes (e.g. nanoliters) onto the column with a high degree of accuracy and precision. In addition, the injection system must contribute minimally to extra-column peak broadening.

Figure 5 Schematic of a syringe pump.

Figure 6 Schematic of an injection valve.

The most common means of sample injection in micro LC are microvalve injectors, such as those produced by Valco (Houston TX, USA) and Rheodyne (Cotati CA, USA). In this type of device, depicted schematically in Figure 6, an internal loop of fixed volume controls the amount of sample injected. Injection volume is varied by changing the sample loop. Injection loops are available commercially from a number of manufacturers in volumes ranging from 60 nL to 1 μL.

The flow geometry and low volume of these injectors permits clean and thorough sweeping of the loop volume, which minimizes peak broadening and tailing.

4.2.3 Detectors

A variety of detection schemes have been employed in micro LC, the most common of which include UV, fluorescence, electrochemical, and mass spectrometric detection. Of these, the optical methods, UV and fluorescence, are the most widely used. With optical detection, the flow cell design is vital in controlling extra-column band broadening; specifically, cell volumes must be extremely small. Ideally, the cell volume should be less than one-tenth of the peak volume;[42] however, decreasing cell volume will generally decrease the detection path length, which reduces sensitivity in accordance with the Beer–Lambert relationship. Thus, optimizing cell design generally involves a compromise between sensitivity and efficiency.

Optical detection in capillary LC can be performed using the capillary column itself as the flow cell. In this mode, known as on-column detection, a small section of the polyimide coating of the capillary is removed downstream from the packed bed, rendering it UV transparent. Incident radiation is directed through a slit, passes through the capillary and strikes a photodetector

Figure 7 Schematic of on-column detection with a packed fused-silica capillary column.

situated opposite the entrance slit (depicted in Figure 7). Advantages of on-column detection include its simplicity and minimal extra-column volume contribution. It is, however, limited by the low sensitivity imposed by the short detection path length.

Alternatively, micro flow cells can be employed with longer path lengths to provide increased sensitivity while contributing only very small volumes to the system. One such cell configuration, available commercially from LC Packings (Amsterdam, the Netherlands), employs a Z-shaped fluid path designed to increase detection path length.

Some limitations of micro flow cells are cost (relative to on-column detection) and problems with coupling to the chromatographic column (e.g. leaks, dead volumes).

Electrochemical detection is particularly attractive for use in micro LC. Used primarily in voltammetric and amperometric modes, electrochemical detection is sensitive, selective, amenable to miniaturization and, in contrast to optical detection, suffers no loss of sensitivity with miniaturized cell volumes. (For a recent review of electrochemical detection in miniaturized separation techniques see Ewing et al.[58]). DLs in the femtomole range have been obtained with voltammetric detection using a carbon fiber microelectrode coupled to a capillary LC column.[59]

Alternatively, on-column detection can be performed with fused-silica capillary columns. On-column detection

Figure 8 Block diagram of a CEC system.

is advantageous primarily owing to its simplicity and minimal extra-column volume contribution. A drawback of this approach, however, is reduced sensitivity due to a substantially reduced detection path length.

4.3 System Components: Capillary Electrochromatography

A block diagram of a typical CEC system is illustrated in Figure 8. The instrument consists of a high voltage (HV) power supply capable of applying a high potential (usually up to 30 kV) and a pair of platinum wire electrodes. The separation capillary is immersed in the inlet and outlet mobile phase reservoirs, forming a complete circuit. In PC CEC, it is usually necessary to pressurize the mobile phase reservoirs in order to minimize the formation of gas bubbles, which can drastically affect EOF.

Sample introduction in CEC is usually achieved via electrokinetic injection. In this technique, the capillary inlet is first removed from the mobile phase vial, immersed into the sample and a voltage applied. The resultant EOF draws a given amount of sample into the capillary. The capillary inlet is then reimmersed in the mobile phase vial and the separation begun. In contrast to capillary LC, in which a known volume of sample is injected by means of a valve, the injection volume in CEC must be determined indirectly from the injection time and the EOF velocity at the voltage used. Because of this, the injection precision is dependent upon the stability of the EOF. Not surprisingly, injection to injection reproducibility tends to be lower in CEC than in capillary LC.

CEC instrumentation is virtually identical to that used in CE, with the exception of external pressurization, a minor modification. This is an added advantage for CEC in that both separation techniques can be performed on the same instrumentation.

Optical detection in CEC is generally in the on-column format. This requires that a detection window be made (as in capillary LC) by removing a small section of the polyimide cladding. As in capillary LC, low detection sensitivity imposed by short cell path lengths is an issue

in CEC. Specially designed detection cells including ''Z-cells'', ''bubble cells'' and the High Sensitivity Detection Cell® marketed by Hewlett–Packard provide increased path lengths, which improve DLs.

Low sensitivity, a major disadvantage of CE, is less a problem in CEC owing to increased sample capacity. The packed bed provides a high surface area of stationary phase on which sample can be accommodated. As a result, CEC allows for larger volume injections without compromising efficiency.

The most common detection scheme in CEC is on-column UV. Alternatively, on-column laser induced fluorescence (LIF) is a highly sensitive technique that provides some compensation for the short detection path lengths. DLs as low as 10^{-11} M were obtained for a series of polycyclicaromatic hydrocarbons (PAHs) using CEC/LIF.[60] As discussed in the next section, mass spectrometric detection has been combined with CEC with excellent results.

4.4 Mass Spectrometry Coupling

4.4.1 Micro Liquid Chromatography/Mass Spectrometry

Interfacing a mass spectrometer to a chromatograph can provide a wealth of analytical information. In addition to mass-selective detection, a mass spectrometer can yield structural information that can be used to identify compounds as they elute from the column. In spite of the advantages gained by combining the techniques, interfacing LC to MS has been hampered by practical problems. In contrast to GC/MS, it is only since about 1985 that LC/MS has grown into a widespread technique, with the advent of improved interface and ionization source technology, in particular electrospray ionization (ESI).

The chief problem in coupling LC to a mass spectrometer is the incompatibility that results from the relatively large volumes of effluent from the LC column and the vacuum requirement of the mass spectrometer. Ideally, the LC effluent should be vaporized and the solvent vapor pumped out of the system prior to the gas-phase solutes entering the environment of the mass spectrometer. Eliminating the large volumes of solvent vapor generated by 4.6-mm columns is difficult. Consequently, reducing the volumetric flow through the LC system facilitates coupling of the systems. Thus, with respect to flow rates, micro LC is a more natural match for MS than conventional LC. This, in addition to the inherent advantages of miniaturized columns described earlier, has led to the emergence of micro LC/MS as a powerful analytical tool. (For a thorough review of the theory and practice of capillary LC/MS, see Tomer et al.[61])

Currently one of the most popular means of interfacing micro LC to MS is via the ESI source. In the typical ESI arrangement, the sample solution passes through a metal capillary tube, to which is applied a potential on the order of 3–5 kV with respect to a grounded counter electrode a short distance from the tip. Electrostatic repulsion results in the ejection of a stream of charged droplets from the capillary tip. Ionized sample molecules, at atmospheric pressure, are desolvated with the aid of a stream of warm nitrogen gas. The gas phase sample ions enter the low-pressure environment of the mass spectrometer through a series of skimmers. Because no sample heating is required, ESI is well suited for application to large, thermally labile molecules (such as many biomolecules). A soft ionization source, ESI yields predominantly molecular ions. For structural elucidation, ESI is often combined with triple quadrupole mass analyzers in which collision-induced dissociation (CID) is employed to induce fragmentation. Typical solution flow rates for ESI are $1–10\,\mu L\,min^{-1}$. Pneumatically assisted ESI or ion spray, in which a nebulizing gas is employed to assist droplet formation, can accommodate higher flow rates, up to $100–300\,\mu L\,min^{-1}$. These flow rates are directly compatible with miniaturized HPLC columns; flow splitting of the column effluent, which reduces sensitivity, is usually not required.

The high mass sensitivity of micro LC facilitates the analysis of volume-limited samples. For this reason, capillary LC/MS is especially useful for biological samples. In particular, capillary LC/ESI/MS has been utilized extensively in protein and peptide analysis.[62–67] The high resolving power of capillary LC is used to separate complex mixtures of peptide digests, which are subsequently sequenced using tandem MS. One of the most important advantages of the capillary LC format in these sequencing analyses is that only very small amounts of starting material are required. Sequences of peptides have been obtained via capillary LC/ESI/MS with as little as 800 fmol of sample.[64]

Capillary LC/ESI/MS has been employed to study the various peptides that bind to class I major histocompatibility complex molecules.[63] Recognition of these bound peptides by cytotoxic T lymphocytes is an important component of the immune response of the body. Peptide fractions were separated by reversed-phase capillary HPLC and sequence information was obtained by tandem MS using a triple quadrupole instrument. Peptide sequences were obtained with as little as 900 fmol of sample.

Improvements in ESI detection sensitivity gained by reducing column diameter have been demonstrated by Banks.[65] Using a time-of-flight mass spectrometer, measured signal-to-noise (S/N) ratios increased 428-fold upon decreasing column diameter from 2.1 mm to 0.1 mm. A mass DL of 2.5 fmol was obtained for cytochrome-C using the 0.1-mm capillary. Figure 9 is a separation of a mixture containing five proteins (25 fmol each) in less than 7 min using this instrument.[65] These results underscore the power of capillary LC/MS.

Figure 9 Total ion chromatogram of a protein mixture (25 fmol each) obtained with a 100-μm ID HPLC column. (Adapted from Banks, *J.Chromatogr., A*, **786**, 67–73.[65] Copyright (1997) with permission of Elsevier Science.)

4.4.2 Capillary Electrochromatography/Mass Spectrometry

The volumetric flow rates of PC CEC (typically $0.5–2\,\mu L\,min^{-1}$) are also ideal for coupling to MS, in particular ESI. For the analysis of neutral solutes, coupling CEC to MS is more straightforward than MEKC because the latter requires relatively high concentrations of surfactants, which in general are incompatible with most MS interfaces.

Since the mid-1990s, several research groups have been active in developing CEC/MS. In 1994, a 50-μm capillary packed with 3-μm particles was coupled to a mass spectrometer using a fast atom bombardment (FAB) interface.[68] The system was used to analyze a series of steroids. In this instrument, the separation capillary was connected to the MS by means of a transfer capillary, which degraded the chromatographic efficiency of the system owing to the extra-column volume contribution of the transfer line. Schmeer et al.[69] coupled 100-μm ID CEC columns directly to an ESI/MS without the need for a transfer capillary. The outlet end of the separation capillary was positioned directly inside the inner steel needle of the ESI source, eliminating the postcolumn peak broadening that occurs with transfer lines. Although supplementary pressure was employed to stabilize the flow rates, bulk flow was generated mainly by EOF. The instrument was used to separate peptide mixtures at picomole levels.

A few of the other applications of CEC/MS to date are the analysis of textile dyes,[70] pharmaceuticals[71] and DNA adduct mixtures.[72]

CEC/MS is a technique with much promise. The ability to analyze very small sample volumes and the high peak capacity of CEC in combination with the sensitivity and selectivity of MS yields a powerful microanalytical technique.

5 OPTIMIZATION OF ANALYSIS

In order to achieve the ''optimum'' solution to a particular separation problem, numerous aspects must be considered: analyte structure and matrix complexity, nature of the stationary phase, type of column (capillary or conventional, OT or PC), detection sensitivity and operating conditions (such as mobile phase composition, temperature and pressure).

5.1 Selectivity Optimization

The trends in stationary-phase evolution for micro LC and CEC are similar to those in conventional LC: development of stationary phases able to affect chiral separations or screen components of combinatorial libraries or other complex mixtures.

An interesting approach involves the use of molecular imprinted polymers (MIPs). Specific functional monomers interact through covalent or noncovalent interactions with complementary groups of a template molecule. In a subsequent polymerization step cross-linking polymers react with the monomers and create a macroporous matrix. Extraction of the template leaves cavities complementary to the imprint molecule in both shape and chemical functionality. Prepared in bulk, followed by subsequent grinding and sieving, or prepared in situ, resulting in MIP monolithic columns, or produced as spherical beads, the molecularly imprinted polymers provide extremely selective materials for HPLC and electro-driven separation techniques.

Much effort has been invested in designing MIPs suitable for CEC since the increased efficiency specific to this technique is expected to minimize to an extent the band broadening often encountered in separations using MIPs. Promising results have been obtained in the OT/CEC format where baseline separation of D- and L-dansyl phenylalanine was achieved.[73] Other successful approaches consider the macroporous monoliths, which

demonstrated commercial potential by providing the enantioseparation of phenylalanineanilide[74] and β-adrenergic antagonists propranolol and metoprolol.[75]

5.2 Gradient Separation and Temperature Programming

When separating analytes having substantially different capacity factors, the peaks that elute early tend to be poorly resolved while those that appear later in the chromatogram are broadened, a phenomenon known as the ''general elution problem''. Solutions to the general elution problem generally employ establishment of a gradient in one (or more) of the following: solvent strength (gradient elution), viscosity (temperature programming) flow velocity (flow programming), and so on. In gradient elution the strength of the mobile phase is continuously increased during a run, while in temperature programming the viscosity of the solvent decreases as the temperature of the capillary situated in an oven is gradually raised. In CEC increasing flow velocity can be accomplished readily by programming a gradual increase in the applied potential.

The generation of reproducible controlled solvent gradients in capillary columns is not an easy task considering the small flow rates (submicroliter per minute) that must be delivered. In CEC the problem becomes even more complex for instrumental design considerations, since in addition to the delivery of a solvent gradient, a high voltage must be applied simultaneously, and from a chromatographic point of view, because variations in solvent composition significantly affect EOF velocity.

One of the first approaches considered the supply of a pressure-driven gradient in parallel with application of high electric field.[76] In order to take advantage of the high efficiency offered by CEC, the separation must be performed using solely EOF. Therefore, the most embraced approaches consider designs that use HPLC pumps to deliver mobile-phase gradients to the inlet of the separation column.[77,78] Mixtures of drugs,[78] PTH (parathyroid hormone)-aminoacids (from the Edman degradation of a peptide) and steroid hormones[77] were resolved using a mobile-phase splitting device.

Another type of gradient elution system proposed for CEC provides a pure electroosmotically driven flow.[79] It is composed of two fused silica capillaries each connected to a programmable high-voltage power supply and to a different mobile phase reservoir. The applied voltages are varied during the run such that as the flow of one mobile phase increases (as the corresponding potential increases) the amount of the other mobile phase decreases (the applied potential decreases) in a manner that ensures a constant resultant flow. The outlets of the solvent delivering capillaries are attached through a T connector to the inlet of the separation column. System feasibility was proven when 16 PAHs were separated in less than 90 min.

As opposed to conventional LC columns, capillary columns have a small heat capacity, which confers another advantage: the use of temperature programming. The simplicity of the instrument requirements (an oven with temperature control) allows the consideration of temperature programming as a replacement for or augmentation of gradient elution for thermally stable analytes. A comparative study[80] was performed on reversed-phase packed capillaries for separations of alkylbenzenes at temperatures varying from 30 to 80 °C and mobile phases of 60–80% acetonitrile in water. The results indicate that a 5 °C change in column temperature is equivalent to 1% change in acetonitrile concentration. Thus, temperature programming can be used alone or in conjunction with gradient elution to tune the separation of closely eluting compounds finely.

The issue of temperature programming is a bit more complicated in CEC since, besides retention factors, changes in temperature have a considerable effect on the viscosity of the mobile phase, thus on the EOF. Moreover, when working with relatively volatile solvents it is desirable to operate at decreased temperature in order to avoid bubble formation, which has a dramatic effect on the EOF. However, it has been shown that by raising the temperature 25–50 °C the enhancement of mass transport provides a three-fold increase in separation speed.[80]

5.3 Ultra High-pressure Micro Liquid Chromatography

Since the mid 1980s numerous aspects of micro LC and CEC instrumentation have been studied, and pressure or voltage limits once considered fixed have been pushed further in an attempt to increase the performance of miniaturized systems.

Jorgenson, MacNair and Lewis have indicated a possible new direction in micro LC development, the use of extremely high pressure.[81] It has long been recognized that small particles can significantly decrease plate height, though they simultaneously generate large back pressures which impede the use of long columns and increase analysis time by dictating lower flow rates. By using pressures as high as 1400 bar (20 000 psi), Jorgenson et al. obtained reduced plate heights of 1.4 for 66-cm long packed capillaries, accompanied by a significant reduction in the analysis time.

6 APPLICATIONS

6.1 Micro Liquid Chromatography

Micro LC has been employed in a variety of different applications. A number of textbooks and literature

reviews[4,82] present thorough discussions of the various analytical problems to which micro LC has been applied. In this space, only a small sample of these is presented; the interested reader is referred to the cited literature for a more detailed listing.

An interesting application of micro LC that exploits the technique's small volume requirement, is the analysis of single biological cells. In 1992, Jorgenson et al. published a method in which the catecholamines norepinephrine and epinephrine were determined in a single bovine adrenomedullary cell.[83] These authors employed 42 and 50-μm ID fused-silica capillary columns packed with 5-μm C_{18}-coated silica particles. Amperometric detection, which was employed using a carbon fiber microelectrode, yielded DLs in the attomole range. A chromatogram obtained from a single adrenomedullary cell is shown in Figure 10. This research group also published a method for the analysis of single neurons using OT LC in 1989.[59]

Separations of enantiomers are becoming increasingly important and present tough challenges to analysts. One approach to chiral separations in LC is to use a conventional stationary phase and add a chiral selector (e.g. cyclodextrins) to the mobile phase. One of the disadvantages of this approach is that these additives are often quite costly. However, the very low column volumes and solvent consumption rates of miniaturized columns facilitate the use of expensive additives because only a very small amount is required. In a paper by Takeuchi et al.,[84] capillary LC with a cyclodextrin additive was employed to obtain separations of 1-ferrocenylethanol and dansyl-phenylalanine enantiomers. In this method, 350-μm ID capillaries were packed with 5-μm ODS (octadecylsilane)-5 particles. Various amounts of methylated β-cyclodextrin were added to the aqueous acetonitrile mobile phase. A separation of ferrocenylethanol enantiomers is shown in Figure 11.

Figure 10 Chromatogram from a single bovine adrenomedullary cell obtained with a packed capillary HPLC column and electrochemical detection. NE is norepinephrine, AA is ascorbic acid (added to samples as an antioxidant), E is epinephrine and DHBA is (3,4-dihydroxybenzyl)amine (internal standard). These peaks correspond to 13.4 and 149 fmol of NE and E, respectively. (Adapted with permission from Cooper et al.[83] Copyright (1992) American Chemical Society.)

A short listing of micro LC applications is presented in Table 6.

6.2 Capillary Electrochromatography

CEC is a relatively new technique that is receiving a great deal of attention from analytical chemists. For this reason, the number of publications on CEC is growing rapidly, as are its applications. A review by Bartle et al. includes a comprehensive listing of CEC applications up to the end of 1996.[90] In addition to those discussed below, a few applications of CEC are presented in Table 7.

Published in 1995, the separation of 16 PAHs shown in Figure 12 demonstrates the separation power of CEC.[60] PAHs are environmental contaminants classified by the US Environmental Protection Agency as "priority" pollutants. This separation was performed with a 75-μm capillary packed with mixture

Table 6 Applications of micro LC

Compounds	Column ID (μm)	Stationary phase	Detection	Comment	Ref.
β-Lactam antibiotics	320	7–8-μm perfusion	ESI/MS	Analyzed in milk	85
Prostaglandins; steroids	240	3-μm ODS	Fluorescence	Analyzed in plasma	87
Bile acids	260	5-μm	Fluorescence	Analyzed in serum	4
Diltiazem and metabolites	320	5-μm C_{18}	UV	Analyzed in plasma	88
Retinoids	180	3-μm C_{18}	Electrochemical	Analyzed in serum	89
Neurotransmitters; amino acids	15–20	Dimethyloctadecylsilane (OTLC)	Electrochemical	Single neuron analysis	20

Table 7 Applications of CEC

Compounds	Column ID (μm)	Stationary phase	Detection	Comment	Ref.
Tricyclic antidepressants	50	3-μm ODS	UV	$>8 \times 10^6$ plates m^{-1}	91
Triglycerides	100	3-μm ODS	UV	$h < 2$	92
PAHs	75	3-μm ODS	LIF	$1.0–1.5 \times 10^5$ plates obtained	60
Hydroxybenzoates	25	Polymethacrylate (OT/CEC)	UV	In situ polymerization of stationary phase	49
Tetracyclines	50	C_{18}	UV	Stationary phase covalently linked to wall	93
Corticosteroids	50	3-μm ODS	UV	Analyzed in urine and plasma	94

(90 : 10) of 3-μm ODS and 1-μm nonporous silica. On-column LIF detection yielded mass DLs on the order of 10^{-19} mol. Efficiencies of 100 000–150 000 plates m^{-1} were obtained.

In 1997 Euerby et al. published a paper on the applications of CEC in pharmaceutical analysis.[86] Here, this group reported separations of a variety of compound classes including peptides, nucleotides, steroids, diuretics and acidic drugs. Figure 13 illustrates a separation of four commonly used diuretics performed on a commercially available 3-μm CEC Hypersil™ C-18 capillary. Efficiencies ranging from 149 000 to 344 000 plates m^{-1} were obtained.

An interesting application of CEC was recently reported in which inorganic ions were separated by ion exchange capillary electrochromatography (IECEC).[95] Anions such as I^-, IO_3^- and TcO_4^- are often present in nuclear waste materials in locations such as the US Department of Energy site at Hanford, Washington (USA). For this reason, the analysis of such ions constitutes an important environmental application. In this IECEC method, silica-based particles modified with an anion exchanger, 5-μm Nucleosil™ SB, were packed into 75-μm fused-silica capillaries. UV detection was employed to analyze iodide, iodate and perrhenate (ReO_4^- was used as a surrogate for TcO_4^-). Direct comparisons of the IECEC method with capillary zone electrophoresis (CZE) revealed a 20-fold lower DL for the former owing to enhanced sample capacity. These nuclear waste sites are an increasingly important environmental concern, as leaks from underground storage containers are damaging to the environment. Thus, the need exists for improved analytical techniques with which to monitor these sites. IECEC may provide an alternative to CZE for analyzing low levels of inorganic ions leaching from such sites.

7 FUTURE PERSPECTIVES

In spite of the many advantages afforded by miniaturized chromatographic techniques, it is quite doubtful that micro LC and/or CEC will ever completely supplant conventional scale HPLC as the workhorse in the typical analytical laboratory. A more realistic view is that these techniques are complementary in nature. To be sure, capillary LC will continue to play a central role in biological analyses, especially in protein sequencing. In general, the technique is likely to be employed in cases where sample is volume limited. CEC is currently undergoing a period of intense growth; the number of publications has increased dramatically since 1995. The high separation efficiencies obtained in practice, in agreement with theory, are encouraging. Also promising is the fact that many of the CEC separations reported thus far have employed typical HPLC packings, which will simplify method transfer between the techniques. The future of CEC is most likely in applications where high peak capacity is required (e.g. very complex samples), and/or in rapid highly parallel, automated, perhaps chip-based analysis.

Figure 12 CEC separation of 16 PAHs obtained with a 75-μm ID capillary packed with 3-μm C_{18} particles. The peaks are identified as follows: naphthalene (1), acenaphthylene (2), acenaphthene (3), fluorene (4), phenanthrene (5), anthracene (6), fluoranthene (7), pyrene (8), benz[*a*]anthracene (9), chrysene (10), benzo[*b*]fluoranthene (11), benzo[*k*]fluoranthene (12), benzo[*a*]pyrene (13), dibenz[*a*, *h*]anthracene (14), benzo[*ghi*]perylene (15) and indeno-[1,2,3-*cd*]pyrene (16). Normal-phase liquid chromatography (NPLC) is a technique that uses columns packed with polar stationary phases combined with nonpolar or moderately-polar mobile phases to separate the components of mixtures. The rate at which individual solutes migrate through NPLC columns is primarily a function of their polarity. Less polar solutes move the fastest and therefore exit the column and are detected first, followed by solutes of increasing polarity which move more slowly. However, polarity can sometimes play a secondary role relative to a solute's ability to experience a specific interaction with active sites on the stationary phase surface. The importance of these specific solute–stationary phase interactions in NPLC gives it some unique advantages over the more widely practised reversed-phase liquid chromatography (RPLC) technique. RPLC utilizes nonpolar stationary phases and aqueous-based polar mobile phases, and the elution order of solutes in a mixture is related to their hydrophobicity, not polarity; more polar solutes move the fastest and appear first, followed by solutes of decreasing polarity. RPLC is useful for separating mixtures in which components differ in molecular weight and/or water solubility. However, NPLC is preferred for many separation problems, including those in which the water solubility of sample compounds is limited. In addition, NPLC is a better technique for separating compounds that differ in the number or character of functional groups and is particularly useful for separating many types of isomers.

1 INTRODUCTION

1.1 Normal-phase Liquid Chromatography

The extent to which solutes are slowed by interactions with the stationary phase as they move through a liquid chromatography (LC) column is broadly referred to as retention. In NPLC retention is the result of a complicated set of specific molecular interactions, including interactions between the solute and stationary phase, mobile phase and stationary phase, and solute and mobile phase. In NPLC the stationary phase is usually more polar than the flowing mobile phase and the order of retention generally tracks the polarity of components in a mixture: less polar first, followed by solutes of increasing polarity.

The absolute magnitude of retention in a particular NPLC column, as in most LC techniques, is normally controlled by the ''solvent strength'' of the mobile phase. Note that in LC, the mobile phase is often referred to as the solvent. An increase in the solvent strength of the mobile phase results in faster migration of solutes and a general decrease in solute retention times.

In NPLC, solute and mobile phase molecules compete for polar active sites on the stationary phase surface. Changes in mobile phase polarity are thus

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

used to adjust solvent strength and optimize retention times. With modern liquid chromatographs solvent strength is normally controlled by combining a nonpolar weak solvent such as hexane with moderately polar strong solvents such as isopropanol. In binary (or in ternary/quaternary) mobile phases, the weaker solvent is usually designated the ''A'' solvent, while the additional solvent(s) are known as modifiers and designated the B, C, etc. solvents. Generally, increasing the modifier content in the mobile phase increases solvent strength and thus decreases retention.

The relative positions of and spacing between solutes in a normal-phase liquid chromatogram can be optimized through changes in both solvent strength and ''solvent selectivity''. Solvent selectivity refers to the totality of molecular interactions a solvent is capable of, including dispersion, dipole–dipole, and acid–base and hydrogen-bonding interactions. In NPLC, varying the magnitude (solvent strength) or nature (solvent selectivity) of the solvent–stationary phase interactions by changing the mobile phase modifier will affect solute retention. For example, resolution enhancement can often be accomplished by changing from a hexane/isopropanol mobile phase to hexane/dichloroethane, or by changing the amount of a very strong polar modifier such as methyl-*tert*-butyl ether (MTBE) in a hexane/MTBE binary mixture.

1.2 Normal-phase Liquid Chromatography Compared with Reversed-phase Liquid Chromatography

By the mid-1970s, the ability to attach virtually any functional group, polar or nonpolar, to silica particles and make bonded stationary phases led very quickly to the rapid development of RPLC. In contrast to NPLC, RPLC utilizes nonpolar bonded stationary phases (e.g. octadecylsilane (ODS), often abbreviated C_{18}) and aqueous-based polar mobile phases. Retention is based largely on a solute's hydrophobicity, and elution order is thus generally the reverse of that in NPLC: more polar solutes first, followed by solutes of decreasing polarity. RPLC proved to be applicable to a wide variety of separation problems and now represents about 80% of all high-performance liquid chromatography (HPLC) applications. It is useful for separating mixtures in which components differ in molecular weight and/or water solubility.

However, NPLC is still a useful approach for many separation problems, including those in which the water solubility of sample compounds is limited. In addition, NPLC is the preferred mode for separating compounds that differ in the number or character of functional groups, and is particularly useful for separating many types of isomers. Polar bonded phases useful for NPLC are now available, providing a wider array of stationary phase choices than traditional liquid–solid chromatography (LSC) adsorbents such as silica and alumina. Because of the specificity of retention in NPLC, the use of such polar bonded phases in the normal phase mode actually provides a wider variety of optimization choices than are possible with reversed-phase columns.

2 FUNDAMENTALS OF RETENTION

2.1 Liquid–Solid Chromatography: the Adsorption–Displacement Model

The most successful models of retention in LSC are those of Snyder et al.[1–4] and Soczewinski.[5] Both models describe retention as resulting from competitive adsorption between solute and solvent (mobile phase) molecules for active sites on the stationary phase surface. Each assumes a surface monolayer of solvent and/or solute molecules, but Snyder's model further assumes a homogeneous surface so that adsorption energies of both solute and solvent molecules are constant.

The stoichiometry of solute–solvent competition in Snyder's model can be expressed by Equation (1):

$$X_m + nS_a \rightleftharpoons X_a + nS_m \tag{1}$$

where m and a refer to solute (X) and solvent (S) in the mobile and adsorbed phases, respectively. The coefficient n represents the ratio of areas occupied by solute and solvent molecules, respectively, on the adsorbent surface and reflects the fact that a solute molecule must displace all solvent molecules that restrict its access to an adsorption site. The Soczewinski model is similar to Snyder's, but it does not assume a homogeneous surface. Rather, the surface is considered to be energetically heterogeneous, with adsorption occurring entirely at high-energy sites, leading to discrete, one-to-one complexes of the form (Equation 2):

$$X_m + n'S\text{–}A^* \rightleftharpoons n'S_m + X\text{–}A^* \tag{2}$$

where A^* is an active surface site and n' refers to the number of substituents on a solute molecule that are capable of simultaneously interacting with the active sites. Equation (2) thus takes into account the possibility of multisite attachment. By assuming a binary mobile phase consisting of a weak, nonpolar solvent (e.g. hexane) and a strong, polar solvent modifier (e.g. isopropanol), the adsorption of the weak solvent can be ignored and retention predicted by Equation (3):

$$\log k = \text{constant} - n \log N_b \tag{3}$$

Snyder has pointed out a more convenient form of Equation (3) that is equally reliable (Equation 4):

$$\log k = \text{constant} - n \log(\%B) \tag{4}$$

In Equations (3) and (4), k is the capacity factor and N_b the mole fraction of the strong solvent in the mobile phase. The capacity factor is a relative parameter which normalizes solute retention volume (V_r) or retention time (t_r) in terms of column void volume (V_m) or void time (t_0) (Equation 5):

$$k = \frac{V_r - V_m}{V_m} = \frac{t_r - t_0}{t_0} \tag{5}$$

Equations (3) and (4) predict that a plot of $\log k$ against $\log N_b$ or $\log(\%B)$ should yield a straight line. In the Snyder model, the slope of this line should be the ratio of the molecular areas of solute and solvent, whereas Soczewinski's model predicts that the slope is the number of strongly adsorbing substituent groups on the solute.

2.2 Localization and Secondary Solvent Effects

Neither the Snyder nor Soczewinski model is entirely satisfactory as presented for describing retention in NPLC, particularly when bonded stationary phases are used. Such normal bonded phase (NBP) LC columns do contain strongly adsorbing active sites (Soczewinski model), but solute molecular area, not just polar substituents, is known to play an important role in competitive adsorption (Snyder model). In addition, neither model accounts for so-called secondary solvent effects. These effects, which arise from solute–solvent interactions in both the mobile and adsorbed phases, lead to some very useful changes in retention. A rigorous description of retention in NPLC, and thus separation optimization, must therefore include some discussion of the highly specific solute–stationary phase, solvent–stationary phase, and solute–solvent interactions encountered with the types of polar surfaces and molecules commonly used in NPLC. Detailed reviews of these effects can be found in Snyder[6] and Dorsey and Cooper.[7]

Localization refers to the phenomenon which occurs when the strength of strong polar interactions (e.g. dipole–dipole, hydrogen bonding) between solute or solvent molecules and active sites on the stationary phase surface exceed the thermal energy of solute or solvent. When this happens, the solute/solvent molecules are preferentially located in the vicinity of the active site, rather than delocalized in a surface monolayer. The competition between solutes and solvent molecules for localized positions on the stationary phase leads to delocalization of previously localized molecules.

Localization phenomena give rise to some of the most interesting and useful retention behavior in NPLC. For example, it has been established that, at least for solid adsorbents such as silica and alumina, solvent localization is more important in determining mobile phase selectivity than a solvent's acidity, basicity or dipolarity. Snyder has presented a solvent optimization strategy that is largely based on these localization effects.[8] It should be noted that this delocalization competition occurs between solutes and the polar modifier, since the weaker solvent (normally hexane) does not localize.

Figure 1 Representations of various delocalization processes in NPLC. (a) Site-competition delocalization. (b) Restricted-access delocalization. (c) Mixed-site delocalization. Active sites on the stationary phase surface are represented by small, clear circles; polar solute molecules by large, shaded spheroids; polar solvent modifier molecules by stippled circles; and residual silanols by shaded circles on the surface. (Reproduced by permission of the American Chemical Society from J.G. Dorsey, W.T. Cooper, *Anal. Chem.*, **66**, 857A–867A (1994).)

There are actually a number of different types of localization commonly encountered in NPLC, and these are depicted in Figure 1.[7] Site-competition delocalization occurs when localizing polar solutes and modifier molecules have unrestricted access to the active surface site. In this case, an increase in modifier content in the mobile phase will weaken solute localization and retention will decrease to a greater extent than predicted from a solvent strength value determined with nonlocalizing solutes. For example, MTBE, like most basic, localizing solvents, produces a stronger mobile phase than predicted when used with silica and certain bonded phase columns. Correcting for such an effect is straightforward because the solvent strength of the modifier can be adjusted. However, this must be done on a specific solvent–stationary phase basis. The necessary solvent strengths and/or corrections for the most widely used normal-phase columns and polar modifiers have been tabulated.[8,9]

Restricted-access delocalization (Figure 1b), which occurs when polar modifier and solute molecules compete for localization on rigid, fixed surface-active sites where

access is highly limited, is more difficult to predict and quantify. When the modifier content is low it will localize and disrupt solute localization and the effective solvent strength of the modifier will be relatively large. However, with increasing coverage of the adsorbent surface, a point is reached at which adsorbed modifier molecules interfere with further modifier localization. The effective solvent strength of the modifier thus decreases with increasing surface coverage. Since this decrease in modifier solvent strength is non-linear, a simple modification to modifier solvent strength is not suitable. Rather, a delocalization function is required which can be used to adjust the modifier solvent strength.[10–12]

A localization effect that is unique to bonded-phase adsorbents is mixed-site delocalization. This occurs because unreacted, ''residual'' silanol groups (Si–OH) on the underlying silica support can influence the character of the bonded phase through hydrogen bonding with its polar functional group. This hydrogen bonding can be disrupted by the presence of strongly localizing modifiers (Figure 1c). This mixed-site delocalization effect is most pronounced in weaker, less polar bonded phase columns such as cyano-silica.[13]

Secondary solvent effects arise from specific, polar interactions between solute and solvent molecules. While they are normally considered ''secondary'' in their importance on retention relative to solute–solvent–stationary phase interactions, they often provide an effective means of altering retention selectivity. There are three different types of solvent effects observed in NPLC. The first and most straightforward occurs in the mobile phase when there is a specific polar interaction between solutes and the mobile phase modifier. This type of solvent effect, which is not balanced by a corresponding effect in the stationary phase, decreases retention of the interacting solute and is thus considered a negative effect.

A second type of solvent effect is observed when there is a strong affinity between the stationary phase and polar modifiers, resulting in an excess concentration of modifier in the surface adsorbed layer. If a solute experiences a strong interaction with this modifier, and the concentration of modifier is higher in the stationary phase than in the mobile phase, the solute–solvent interaction will increase retention. This second type is thus considered a positive effect because it increases retention.

The third type of solvent effect is also due to excess modifier in the stationary phase, but in this case the modifier is so strongly adsorbed it is sterically hindered from interacting with an adsorbed solute which is nonetheless experiencing a strong interaction with the modifier in the mobile phase. This unbalanced interaction decreases retention and is thus a negative effect.

3 STATIONARY PHASES

3.1 Solid Adsorbents

Silica gel is by far the most popular stationary phase for LSC. Its rigidity provides structural stability at the high pressures used in HPLC and it can be synthesized with a wide variety of particle sizes, surface areas, and pore diameters. For analytical separations, 5–10 μm porous silica is most commonly used, but larger silica with less porosity can be obtained.

In addition to its advantageous physical attributes, silica provides a very polar surface with a high concentration of active sites. The active sites on silica are Si–OH groups (silanols), and most chromatographic-grade silicas have Si–OH concentrations of $\sim 8\,\mu mol\,m^{-2}$. Unfortunately, not all silanols are identical, which leads to a significantly heterogeneous surface and, in many cases, ''peak tailing'' of highly polar solutes. For this reason, small amounts of water are often added to NPLC mobile phases to deactivate the higher-energy silanols.

Silanols are weakly acidic (pK_a 5–7), and thus care in the choice of the type of silica is necessary if basic solutes are to be separated. So-called Type A silicas contain a high concentration of highly-acidic ''free'' silanols and are thus not appropriate stationary phases for strongly basic solutes unless special conditions are employed. Type B silicas are dominated by less acidic geminal and associated silanols. Columns made from these Type B silicas have been shown to be useful for normal phase separations of highly polar and basic solutes.[14]

For samples that are strongly basic or acid-sensitive, alumina is the adsorbent of choice. Alumina is weakly basic, and strongly acidic and base-sensitive compounds cannot normally be chromatographed on it. Retention of neutral solutes is similar on alumina and silica, but alumina lacks many of the physical attributes of silica that have led to silica's prominence. Thus, unless precluded by its acidic character, silica is normally the LSC stationary phase of choice.

Other adsorbents which have been suggested as possible alternatives to silica and alumina include zirconia and titania. Both of these solids appear to be more basic than silica, much like alumina.[15] While each has some unique chromatographic properties, neither adsorbent is widely used today.

3.2 Bonded Phases

Chemically-bonded stationary phases have two distinct advantages over solid adsorbents for NPLC. First, derivatization of silica gel with a polar organic functional group provides a much more homogeneous surface than bare silica. Even though steric hindrance by adjacent ligands normally prevents complete reaction

of all surface silanols, a bonded phase packing is much more homogeneous than bare silica and deactivation procedures such as addition of water to the mobile phase are no longer necessary.

A second, more subtle, but ultimately more significant advantage of NPLC bonded stationary phases is that they allow chromatographic selectivity to be enhanced through adjustment of both the stationary and mobile phases. Because retention in NPLC is governed primarily by competitive solute–stationary phase and solvent–stationary phase interactions, changing the column as well as the mobile phase can optimize absolute and relative retention of solutes in a mixture. This is in contrast to RPLC, where the stationary phase, while not a completely passive participant in retention, is nevertheless much less important than the mobile phase.

Virtually all NPLC bonded phases are prepared by reacting a monochloroalkylsilane with silanols on the surface of silica gel. This reaction results in an alkylsilane attached to the silica surface via a silyl ether bond (Si–O–Si). The desired functional group used to produce the specific character of the bonded phase is located at the end of the alkyl chain opposite from the ether bond. The alkyl chain is referred to as the ''spacer''; in NPLC these spacers are normally only 2–3 carbon atoms in length.

The most widely-used NPLC bonded phases are cyanopropyl-silica (cyano), aminopropyl-silica (amino), and 1,2-dihydroxypropyl-silica (diol). In addition, a number of other functional groups have been used to produce highly selective NBP columns (e.g. phenylpropyl columns are useful for some highly specific applications). However, the cyano-, amino-, and diol-silica columns are now the most popular. This is due in great part to their widely different retention characteristics and moderate polarity.

Figure 2 Stationary phase selectivity triangle formed by the combination of diol-, amino- and cyano-silica NBP columns.

The diol column is acidic, the amino column moderately basic, and the cyano column a moderate dipole–dipole interactor. These three columns together provide virtually all the retention characteristics necessary for efficient optimization of sample resolution. It has even been suggested that these three phases form a ''stationary phase selectivity triangle'' similar to the solvent selectivity triangle used to pick mobile phase solvents (Figure 2).[4,16] In chromatography, a selectivity triangle is used as a guide for producing the most dramatic changes in chemical characteristics of mobile and/or stationary phases during optimization experiments. Cyano, diol and amino columns appear to provide these dramatic differences in retention characteristics.

4 MOBILE PHASES

4.1 Common Solvents Used in Normal-phase Liquid Chromatography

A wide variety of organic solvents have been used as mobile phases in NPLC, ranging in polarity from fluorocarbons to methanol. Liquids with low boiling points and low viscosities are preferred. In addition, it should be noted that in normal-phase chromatography the mobile phase should be less polar than all sample components. In recent years there has been a tendency to choose from a rather limited number of available solvents, making solvent optimization more efficient. Hexane (or pentane) has become the nonpolar solvent of choice, although isooctane is sometimes used. For very nonpolar samples, fluorocarbons may be required.

Most NPLC separations require a mobile phase more polar than hexane. While this can be accomplished with a single solvent, it is actually more convenient to combine hexane with a much stronger solvent and adjust the relative proportions of the two solvents to obtain the correct solvent strength. In such binary mixtures, hexane is the weak solvent (normally designated the A solvent) and the polar solvent the strong solvent (the B solvent). The strong solvent is also frequently referred to as the ''modifier''. Solvents commonly used as modifiers include chloroform, methylene chloride, dichloroethane, ethyl acetate, MTBE, tetrahydrofuran (THF), and alcohols such as methanol or isopropanol. When very strong (i.e. very polar) mobile phases are required, hexane can be omitted and one of the polar modifiers used alone or in combination with another modifier.

4.2 Solvent Strength

Retention in NPLC is determined by competitive adsorption between solute and solvent molecules at the stationary phase surface. Thus, the greater the affinity of

the solvent for the stationary phase, the greater is its solvent strength. However, because of the polar interactions involved in NPLC and the specific localization effects that result, a solvent's apparent strength can vary from column to column. There is thus no absolute scale of solvent strength in the normal-phase mode that is useful for all the different columns available. However, a number of empirical scales are available for predicting and/or controlling retention. In LSC the adsorption solvent strength parameter ε^0 is most useful. This parameter is defined as the adsorption energy per unit cross-sectional area of solvent. Table 1 contains ε^0 values for commonly used normal-phase solvents.[8] For normal bonded-phase LC, empirically-determined solvent strengths have been published for dichloromethane, chloroform and MTBE when used with cyano, amino and diol columns.[9] These solvent strengths are summarized in Table 2.

As noted, it is much more convenient to mix solvents of different polarity in the correct proportions than to find a single solvent of just the right solvent strength and selectivity. This involves combining a nonpolar solvent with a polar solvent which alone would be too strong. These two solvents are then blended empirically to give the correct solvent strength and optimum range of solute capacity factors. Unfortunately, solvent strength in NPLC is not a linear function of the volume percent of modifier in the mobile phase, but is described by Equation (6).

$$E_{ab} = E_a + \frac{\log[N_b 10^{\alpha n_b (E_b - E_a)} + 1 - N_b]}{\alpha n_b} \qquad (6)$$

Here, E_{ab} is the solvent strength of the mixture, E_a and E_b the pure solvent strengths of solvents a and b, respectively, N_b the mole fraction and n_b the molecular area of the modifier, and α an adsorbent activity factor normally taken as unity in modern analytical columns. However, Equation (6) can be greatly simplified if hexane is the weak solvent (A) and the fraction of modifier (B) is not too low (Equation 7).

$$E_{ab} = E_b + \frac{\log N_b}{\alpha n_b} \qquad (7)$$

Careful examination of Equation (6) or (7) reveals that binary solvent strengths increase rapidly with increasing modifier content at low modifier levels and less dramatically at higher modifier levels.

It is sometimes necessary to change the polar B solvent to optimize solvent selectivity (see next section). When carrying out such selectivity optimization experiments it is convenient to maintain a constant solvent strength E_{ab}. This can be accomplished by using Equation (6) or (7) and the appropriate solvent strengths and physical parameters. Alternatively, published solvent-strength nomographs provide the same information for silica[17] and cyano or amino bonded-phase columns.[8]

Table 1 Solvent strength values of some common normal-phase solvents when used with solid adsorbents[a]

Solvent	Solvent strength, ε^0	
	Silica	Alumina
Heptane	0.01	0.01
Hexane	0.01	0.01
Isooctane	0.01	0.01
1-Chlorobutane	0.20	0.26
Chloroform	0.26	0.40
Dichloromethane	0.32	0.42
Ethyl acetate	0.38	0.58
THF	0.44	0.57
Acetonitrile	0.50	0.65
Methanol	~0.7	0.95

4.3 Solvent Selectivity

Once the correct solvent strength has been established (i.e. a solvent strength that produces sample capacity factors in the range of 0.5–20[8]), it is frequently necessary to further enhance sample resolution through optimization of solvent selectivity. Solvent selectivity refers to the totality of molecular interactions a solvent is capable of, including dispersion, dipole–dipole, and acid–base and hydrogen-bonding interactions. In NPLC, these molecular interactions are exploited in both the stationary and mobile phases. In the stationary phase solvent localization plays a critical role in determining retention selectivity, particularly when silica columns are used. Specific molecular interactions in the mobile phase generally play a lesser role in controlling selectivity and are thus referred to as secondary solvent effects. However, in the weaker, less polar bonded phase columns (cyano, amino, diol), these secondary solvent effects

Figure 3 Positions and ''inner selectivity triangle'' (———) of common NPLC modifiers useful with bonded-phase columns. Positions and ''inner selectivity triangle'' (- - - - -) of NPLC modifiers useful with solid adsorbent columns.

can sometimes provide selectivity enhancement not obtainable through changes in solvent localization alone.

The fundamental rule of mobile phase selectivity optimization in LC is that the greatest change in selectivity occurs when molecular interactions between solute, solvent and stationary phase are dramatically changed. These dramatic changes in solvent selectivity can be visualized using the selectivity triangle[18,19] which positions solvents in a triangle based on the relative importance of their proton acceptor, proton donor, and dipole–dipole characteristics. The most dramatic changes in solvent characteristics occur when a solvent from one apex of the triangle (e.g. proton donors) is replaced by one from another apex (e.g. proton acceptors). This has led to the use of three modifiers for solvent selectivity optimization in LC. Since these three modifiers represent regions of the selectivity triangle, they are sometimes referred to as the ''inner triangle''. In NPLC, the inner triangle would normally be formed with chloroform (proton donor), MTBE or THF (proton acceptor), and dichloromethane or dichloroethane (dipole). The solvent selectivity triangle with the normal-phase inner triangle superimposed is depicted in Figure 3. This ''inner triangle'' has been shown to produce large selectivity changes in cyano, amino and diol bonded-phase columns.[9,16]

Solvent selectivity in silica columns, however, is dominated by the ability of a solvent to localize. Furthermore, because of the acidic nature of the active sites on silica (silanols), basic localizing solvents show different selectivities than nonbasic localizing solvents. These observations led to an alternative selectivity triangle which emphasizes

Figure 4 Normal-phase separation of cyclopeptide mixture on a polyhydroxyethyl column by hydrophilic interaction chromatography (HILIC). Mobile phase 15 mM tetraethylammonium phosphate (pH 2.8) with indicated percent acetonitrile included for each separation. (Reproduced by permission of Elsevier Science Publishers from A. Alpert, *J. Chromatogr.*, **499**, 177–196 (1990).)

localization effects and includes a basic localizing solvent (MTBE), a nonbasic localizing solvent (acetonitrile or ethyl acetate), and a nonlocalizing solvent (methylene chloride or ethylene dichloride).[20] This localization-based inner selectivity triangle is also included in Figure 3.

4.4 Aqueous Mobile Phases

While most NPLC mobile phases are made of either polar organic solvents or mixtures of a polar and nonpolar solvent, there are some applications where water is an effective additive. It was noted earlier that silica columns are the strongest NPLC stationary phases and are characterized by a wide variety of silanol adsorption sites. Because water binds very strongly to these silanols, small variations in the water content of the mobile phase can lead to dramatic changes in solute retention. These variations in retention can be largely prevented by purposefully adding small amounts of water to the mobile phase.

Aqueous-based mobile phases are also appropriate for very hydrophilic samples that do not easily dissolve in organic solvents. Frequently, special columns are used with aqueous mobile phases resulting in a unique type of normal-phase separation referred to as HILIC. Mobile phase strength is varied by adding a water-soluble organic solvent. Unlike ''normal'' NPLC, however, increasing the polar organic modifier content leads to an overall *increase* in solute retention. This behavior is demonstrated in Figure 4, which contains chromatograms of a cyclopeptide mixture separated on an HILIC column with various water/acetonitrile mobile phases.[21]

5 OPTIMIZATION STRATEGIES

5.1 Mobile Phase Optimization

Mobile phase optimization begins by establishing the correct solvent strength: that is, a solvent strength that yields solute capacity factors in the range of 0.5–20. As noted previously, solvent strength is normally set by mixing a weak solvent with a strong polar modifier. Hexane is the weak solvent of choice unless a very strong mobile phase is required. In such cases a more polar weak solvent such as methylene chloride or MTBE is more appropriate. Solvent strength is optimized through a series of experiments in which the composition of the polar modifier is increased, or alternatively with a gradient elution experiment. Because of the importance of localization effects in NPLC, solvent strength optimization can frequently provide the necessary retention selectivity.

If an appropriate solvent strength and selectivity cannot be found with a single modifier, a change in modifier type is required. This involves choosing a second polar modifier from a different region of the selectivity triangle (Figure 3). This modifier is added to the weak solvent at a level which produces the same optimized solvent strength as the original mixture. The correct level of new modifier can be estimated via Equation (6) or (7), or by using published nomographs.[8,17] In this way the original overall range of sample capacity factors which was optimized in the solvent strength experiments should remain roughly constant but the relative positions of sample components might be altered through localization and secondary solvent effects. If this second solvent mixture still does not provide adequate resolution of all sample components, a third can be tried, again keeping solvent strength constant. Here, the solvent modifier should come from a corner of the selectivity triangle not represented in the first two solvent mixtures.

With silica columns the inner solvent selectivity triangle that emphasizes localization effects produces the most dramatic changes in retention selectivity.[8,19] The dominance of these localization effects in determining the selectivity of polar bonded-phase columns has not yet been established, however. Significant differences in the selectivities of bonded-phase columns have been accomplished with the traditional inner triangle that emphasizes proton donor, proton acceptor and dipole characteristics.[9,16] Thus, the appropriate strong solvents to use when changing modifier type for selectivity enhancement appear to depend on the column type.

As an example of such a mobile phase optimization, imagine that an amino column is chosen to separate the components in a particular sample. Initial solvent strength experiments with hexane and chloroform then determine that a 90 : 10 (v/v) mixture of hexane–chloroform gives the correct capacity factor range. From the data in Dorsey and Cooper[7] the solvent strength of this composition is estimated to be 0.044. A change in selectivity is then accomplished by changing to a hexane/MTBE mixture, and the data[7] indicate that a 80 : 20 hexane–MTBE composition also has a solvent strength of 0.044. Finally, the third solvent mixture would be hexane–dichloromethane at a 90 : 10 ratio, since the solvent strengths of chloroform and dichloromethane are approximately equal when used with an amino column.

A more elaborate mobile phase optimization scheme has been proposed and shown to be effective in developing NPLC separations of very complex mixtures.[22] This approach again begins by establishing the correct solvent strength using a binary mobile phase, either through incremental, decreasing changes in the amount of strong solvent, or through a ''reversed-gradient'' experiment. Then, a series of seven isocratic experiments are carried out in which the three modifiers from an inner triangle are mixed in a systematic way, all the while maintaining an approximately constant solvent strength. In the example cited the separation of a mixture of substituted naphthalenes was developed. Since a silica column was used, the modifiers were chosen from the ''localization'' inner triangle: MTBE (basic localizing),

acetonitrile (nonbasic localizing) and methylene chloride (nonlocalizing). Initial experiments indicated that a 42% : 58% hexane–methylene chloride mixture yielded the appropriate solvent strength. This solvent mixture was then used for the first isocratic experiment. Subsequent experiments with 96 : 4 hexane–MTBE and 87 : 10 : 3 hexane–methylene chloride–acetonitrile followed. Note that the third mixture required methylene chloride as a co-solvent for hexane and acetonitrile. Experiment 4 mixed the mobile phases used in experiments 1 and 2: 77 : 22 : 1 hexane–methylene chloride–MTBE. Similarly, experiment 5 mixed the mobile phases used in experiments 2 and 3 (92 : 5 : 2 : 2 hexane–methylene chloride–MTBE–acetonitrile), while experiment 6 mixed the mobile phases from experiments 1 and 3 (69 : 30 : 1 hexane–methylene chloride–acetonitrile). Finally, experiment 7 mixed all three binary mobile phases used in the initial three experiments: 89 : 9 : 1 : 1 hexane–methylene chloride–MTBE–acetonitrile.

5.2 Stationary Phase Choices

The introduction of bonded phases for use in NPLC allows stationary phase optimization in parallel with mobile phase optimization. It has been suggested that the cyano, amino and diol columns represent a stationary phase selectivity triangle.[4,16] Not only do these columns provide different retention characteristics, they also can induce very significant and unique secondary solvent effects due to preferential adsorption of mobile phase modifiers. Thus, for particularly challenging separations, mobile phase optimizations superimposed on changes in stationary phase selectivity may be required. Figure 5 demonstrates how a change in column alone (silica to a diol bonded phase) can provide adequate separation of a mixture of phenols. Figure 5 also points out the dramatic changes in solvent strength of modifiers – in this case methanol – when used with different stationary phases.

Figure 5 Resolution enhancement through stationary phase optimization. Separation of phenols on bare silica (a) and diol-silica (b). Both columns are 4.6 i.d. × 250 mm, 5 µm particles. Mobile phase: 85 : 15 (v/v) isooctane–ethanol, flow rate 2.0 mL min^{-1}. (Reproduced by permission of YMC, Inc.)

6 TECHNIQUES

6.1 Isocratic Separations

Isocratic separations utilize a single mobile phase composition to elute sample components, in contrast to gradient elution where the mobile phase composition is changed during the course of a separation. The overwhelming majority of LC separations are done isocratically, which is preferred for a number of reasons. First, most mobile phase solvents are not completely transparent to spectroscopic detectors and thus changes in mobile phase composition produce detector ''drift''. In addition, after a gradient elution separation is completed the mobile phase composition must be returned to its original value. This is not as simple as might seem, since the column must also be re-equilibrated with the original solvent mixture, a time- and solvent-consuming procedure.

The introduction of bonded phases for use in the normal-phase mode has greatly increased the opportunities for isocratic NPLC separations. With judicious solvent and/or stationary phase optimization, most sample mixtures can be adequately resolved with a single mobile–stationary phase combination. In addition, many of the benefits of gradient elution can be realized using the column switching and stationary-phase programming techniques discussed below.

6.2 Gradient Elution

In spite of the most exhaustive isocratic optimization efforts, some samples are so complex and contain solutes with such a wide range of sample capacity factors at any mobile phase composition that gradient elution is required. This is known as the ''general elution problem''. At some intermediate value of solvent strength there is insufficient resolution of early-eluting peaks, with extremely long retention of later-eluting peaks. Decreasing solvent strength can increase resolution of the early-eluting peaks, but the result is unacceptably long retention times of the rest of the sample mixture components. Conversely, the strongly-retained solutes can be eluted in a reasonable time by increasing the mobile phase solvent strength, but at the expense of the resolution of the early peaks.

The solution to this general elution problem is to change the capacity factors of solutes during the course of a separation by changing mobile phase composition. This is normally accomplished by using a binary mixture of a weak and strong solvent and increasing the relative proportion of strong solvent as the chromatogram proceeds. A gradient elution separation thus begins with a weak binary solvent mixture that yields capacity factors for early peaks which are sufficiently high for the necessary resolution. Later peaks clearly have capacity factors which are very large and they do not move very far down the column in the first stages of the gradient. However, as the mobile phase increases in strength, the capacity factors of more strongly-retained compounds decrease to the point that they begin to move and eventually elute from the column.

There are a number of very positive benefits that result from gradient elution. The first and most obvious is that a wide range of solutes differing greatly in molecular properties can be separated in a single chromatogram. In addition, since the movement of any solute through the column is significant only when some minimum capacity factor has been reached, most solutes experience roughly the same ''average'' capacity factor during their elution. This means that solute bands elute with approximately equal peak widths. Finally, the gradient elution procedure actually produces a gradient of mobile phase solvent strengths along the column. This means that the back side, or tail, of a solute band will be in a stronger solvent environment than the front. This effect tends to sharpen the bands of polar, strongly-retained solutes which would otherwise be broad due to specific interactions with the stationary phase surface. This last feature of gradient elution is particularly useful in NPLC because of the polar stationary phases commonly used.

Figure 6 Typical gradients used in HPLC.

There are two important considerations when developing a gradient separation: the shape of the gradient and the rate at which the solvent strength of the mobile phase is changed. The most common gradients are depicted in Figure 6. Note that the gradient is usually defined in terms of the change in the amount of strong (B) solvent in the mobile phase. Linear gradients are the most popular, but modern liquid chromatographs are capable of producing a variety of alternative gradients. A convex gradient, which produces a slower rate of change of mobile phase composition at the end of the chromatogram, may be called for if a linear gradient produces adequate resolution of early-eluting peaks but inadequate resolution of later peaks. This situation is sometimes encountered in environmental and petroleum applications when, for example, polynuclear aromatic hydrocarbons are separated by both number of rings and then number of substituents on each ring. Because the number of possible substituents increases with number of aromatic rings, greater resolution is actually needed at the end of the chromatogram, not the beginning.

Of more interest in NPLC are concave gradients in which the rate of change of mobile phase composition is slower in the early stages of the chromatogram, increasing as the chromatogram develops. This type of gradient is often more appropriate for NPLC because of the nonlinear relationship between solvent strength and % modifier (Equation 7). Such a gradient comes much closer to producing a gradient that is linear in solvent strength.

In addition to choosing a gradient type, the optimum rate at which mobile phase composition is changed must be determined. The rate at which the strong modifier is added to the mobile phase is referred to as the gradient steepness and is normally expressed as $\Delta\,\%\mathrm{B\ min^{-1}}$. In the linear gradient depicted in Figure 6 the modifier content changes from 10% to 50% over a period of 20 min: a gradient steepness of $2\%\ \mathrm{min^{-1}}$. Because different modifiers have different pure solvent strengths, they thus produce different solvent strength gradients at fixed steepnesses. Determining the optimum gradient steepness for a particular gradient elution separation normally requires a trial-and-error approach, although Snyder, Kirkland and Glach[8] have provided some guidelines.

One final word about gradients is necessary and is suggested in Figure 6, where none of the gradients begin at 0% B. Because the polar modifiers in NPLC are preferentially adsorbed by nonpolar stationary phases, the first exposure of the stationary phase to the modifier normally produces a rather significant imbalance in mobile and stationary phase concentrations of B. This will continue until the stationary phase is saturated with B such that the proper equilibrium of B between mobile and stationary phases is reached. Furthermore, this imbalance

is most pronounced at very low (<1–5%B) modifier contents. Thus, to produce ''smooth'' gradients, it is always advisable to begin the gradient at some fixed level of modifier in order to saturate the stationary phase.

6.3 Column Switching, Stationary Phase Programming, and Two-dimensional Liquid Chromatography

For all of its advantages, gradient elution LC does have some drawbacks, as noted previously. These drawbacks have led to an interest in exploiting changes in stationary phase strength and selectivity to accomplish the same chromatographic effect produced by gradient elution. Again, the fundamental principal involved is changing the capacity factors of solutes during the chromatogram. NPLC has the advantage over RPLC in this regard because of the ability to change retention mechanisms by changing columns. This is not routinely possible in RPLC where hydrophobic forces dominate retention in all columns.

Column switching refers to the use of multiple chromatographic columns and switching valves to optimize the separation of very complex mixtures. It is a routine practice in gas chromatography and is finding increasing popularity for LC separations. The fundamental advantage of using multiple columns in this way is that isocratic mobile phases can be employed.

Stationary phase programming is one of the most useful forms of column switching and is analogous to gradient elution. It is normally accomplished by combining columns of different retentive strength or activity with a switching valve. The first column has a significantly lower activity than the second. A sample mixture is injected into the first column and rapidly-moving bands made up of nonpolar components are not separated by this first column but are diverted by the switching valve to the second. Once these fast-moving bands have been loaded onto the second column, the valve is switched so that the slower-moving, more strongly retained solutes, which in principal will be separated by the first column, are directed to the detector. After detection of this first set of polar compounds, the valve is returned to its original position, directing solvent back through column 2. The first, less-polar group of solutes is then eluted. Thus, the retention order of solutes 1–6, where 1 was the least polar and 6 the most polar, might be:

$$4 < 5 < 6 \ll 1 < 2 < 3$$

A column switching technique that is more powerful than stationary phase programming and which is made available by the unique characteristics of different NBP columns is two-dimensional (2-D) chromatography. 2-D chromatography is normally thought of as involving sample displacement (elution) in two dimensions that are physically orthogonal to each other. However, if the two displacements are also chemically orthogonal, then the maximum amount of separation space is available. When the two displacements are physically orthogonal the total peak capacity of the system (the maximum number of peaks that can be resolved in a given time window) is the sum of the individual peak capacities of each displacement (Equation 8).

$$n_T = n_1 + n_2 \tag{8}$$

However, when the two displacements are also chemically orthogonal, the overall peak capacity of the system approaches the product of the individual peak capacities (Equation 9).[23]

$$n_T = n_1 n_2 \tag{9}$$

Figure 7 is a schematic representation of a serially coupled NPLC system that can be used to achieve such 2-D separations.[24] The system uses two bonded phase columns that had previously demonstrated different retention selectivities.[9] It also includes two six-port valves. In the ''load loop 1'' position, loading valve L directs effluent from column 1 to sampling loop 1 while at the same time pumping solvent 2 through loop 2 and into the injection valve I. The injection valve I simply directs effluent from loop 1 to waste and solvent 2 through column 2 and detector 2. Here, solvents 1 and 2 are identical. Once the appropriate peak(s) have been loaded in loop 1, the load and injector valves are rotated and the loop–column configurations reversed. Loop 2 is now being filled with the effluent from column 1 while the contents of loop 1 are injected onto column 2.

Figure 8 contains the resulting 1-D (one-dimensional) and 2-D chromatograms using an identical 70 : 30 (v/v)

Figure 7 Schematic representation of system used for on-line 2-D LC. Column 1: aminopropylsilica; column 2: 1,2-dihydroxypropylsilica (diol). (See Hsu[24] for further details.)

Figure 8 2-D NPLC separation of substituted aromatic compounds. Arrows indicate times at which valve configuration in Figure 7 is changed. At first arrow, effluent from column 1, which is stored in loop 1, is injected onto column 2. At second arrow, effluent from column 1 stored in loop 2 is injected onto column 2. NOTE that response characteristics of detectors 1 and 2 are not identical.

mixture of hexane–chloroform in both columns. Note that the 1-D separation of the sample mixture on the amino column (signal produced by detector 1) demonstrates a classic general elution problem. A 1-D separation on the diol column is also not sufficient because chrysene and phenol co-elute. However, by using these two columns in a chemically orthogonal way, all components in the mixture are well-resolved isocratically in less than 30 min.

7 APPLICATIONS

Following are some examples of separation problems that are uniquely suited to NPLC. NPLC is particularly useful in the environmental, biomedical and pharmaceutical fields, since many analytical procedures in these areas begin with extraction of solutes from a polar matrix into a lipophilic solvent. One of the major advantages of NPLC over RPLC is that a solvent changeover is not necessary after such an extraction. For RPLC analyses, solutes in the lipophilic extract must be moved to a polar solvent suitable for the reversed-phase mode.

7.1 Isomers

As noted in the Introduction, NPLC is the preferred mode for separating achiral isomers. The ability of isomeric molecules containing multiple polar substituents to interact with the fixed absorption sites on NPLC columns and experience localization/delocalization effects depends on the geometry of molecules and the positions of the polar groups. Figure 9 provides a dramatic example of the superior effectiveness of NPLC over RPLC for separating a series of retinol isomers.[25]

Figure 9 Comparison of RPLC (a) with NPLC (b) separations of retinol isomers (bands 2–6). (Reproduced by permission of Elsevier Science Publishers from B. Stancher, F. Zonta, *J. Chromatogr.*, **234**, 244–248 (1982).)

7.2 Environmental

The analysis of environmental contaminants in water, soils and foodstuffs is now one of the most common procedures carried out by regulatory agencies.

Figure 10 Gradient elution NPLC separation of Triton-X nonionic surfactants. Column: aminopropylsilica, 4.6 i.d. × 250 mm, 5 μm particles. Mobile phase: A = hexane–2-propanol, 90 : 10 (v/v); B = 2-propanol–water, 90 : 10 (v/v). Gradient: 0–3 min, 97%A/3%B; 53 min, 47%A/53%B at $\Delta 1\%$B min^{-1}. (Reproduced by permission of Supelco, Inc.)

Many of these contaminants are only sparingly soluble in water and are thus extracted from environmental matrices with hydrophobic organic solvents. Resolution of individual components in these extracts is facilitated if the extract can be transferred directly to the separation column. This makes NPLC very attractive for such analyses since these lipophilic extraction solvents are normally compatible with NPLC solvents. Indeed, there are now many descriptions in the literature of automated, on-line extraction and LC separation systems.

Figure 10 demonstrates just such a combination of lipophilic extraction and NPLC for environmental purposes. The nonionic surfactant mixture Triton-X-100 was extracted from water onto a solid-phase microextraction fiber, then desorbed with 97 : 3 (v/v) hexane–isopropanol. The Triton-X mixture in that extract was then separated by gradient elution NPLC using an amino column. The wide range of molecular weights in this Triton-X mixture is a common feature of samples that require gradient elution techniques.

7.3 Biomedical and Pharmaceutical

There are many molecules of biological and pharmaceutical interest that are not only lipophilic, but also require separations based on subtle structural features which are most easily distinguished by NPLC. Fat-soluble vitamins are a good example, since it is very difficult if not impossible to get them dispersed in a reversed-phase solvent. Figures 11 and 12 demonstrate the utility of a normal-phase amino column for such separations. In Figure 11

Figure 11 Separation of tocopherols on an aminopropylsilica bonded phase column. Mobile phase: 70 : 30 (v/v) hexane–ethyl acetate, flow rate 1.0 mL min^{-1}. (Reproduced by permission of Supelco, Inc.)

Figure 12 Separation of Vitamin K isomers on an aminopropylsilica bonded phase column. Mobile phase: 99 : 1 (v/v) hexane–ethyl acetate, flow rate 1.5 mL min^{-1}. (Reproduced by permission of Supelco, Inc.)

various tocopherols (Vitamin D) are easily resolved in less than 10 minutes isocratically. The strength of NPLC for isomer separations is further demonstrated in the chromatogram in Figure 12 in which Vitamin K isomers are cleanly resolved.

While RPLC is normally the choice for separating and purifying peptide mixtures, it is not always the best choice

Figure 13 Comparison of chromatograms of peptides separated on (a) TSK®-ODS reversed-phase and (b) TSK®-Amide normal-phase columns. Chromatogram (a) obtained with 83.3 min linear gradient of acetonitrile–water (0.1% TFA) from 5 : 95 to 55 : 45. Chromatogram (b) obtained with a 70 min linear gradient of water(0.6% TFA)–acetonitrile from 3 : 97 to 45 : 55. (Reproduced by permission of the American Chemical Society from T. Yoshida, *Anal. Chem.*, **69**, 3038–3043 (1997).)

for hydrophilic peptides. Such peptides can frequently be better separated using special normal-phase columns and aqueous-based mobile phases. Figure 13 contains chromatograms of a mixture of peptides separated on reversed-phase and normal-phase TSK® gel columns.[26] The TSK®-Amide normal-phase column clearly provides better resolution and efficiency in less time than the TSK®-ODS reversed-phase column.

ACKNOWLEDGMENTS

The author would like to acknowledge the contributions of the following former graduate students in further developing the science of NPLC: Patty Smith, Scott Boudreau, Leo Hsu and Tim Keefe. He is also grateful for financial support from the US Environmental Protection Agency, Office of Research and Development.

Reversed-phase liquid chromatography (RPLC) is an elution procedure used in liquid chromatography (LC) in which the mobile phase is significantly more polar than the stationary phase, e.g. a microporous silica-based material with chemically bonded alkyl chains. Typically, the mobile phase is a mixture of an aqueous component, often containing a buffer to control pH, and a water-miscible polar organic solvent. This most frequently used mode of LC is suitable for the analysis of compounds with a very wide range of polarities, using experimental variables such as mobile-phase pH and ratio of organic to aqueous mobile phase components to manipulate selectivity and retention to separate sample components from one another.

1 INTRODUCTION

RPLC is a mode of chromatography in which there is a polar mobile phase and a nonpolar stationary phase. In principle this applies to any chromatographic system in which the mobile phase is more polar than the stationary phase. However in practice there must be a marked difference in polarity between the phases for significant chromatographic retention to be obtained. Accordingly, the most common form of RPLC is that in which the mobile phase is a mixture of an aqueous component, often containing a buffer to control pH, and a water-miscible polar organic solvent and the stationary phase is an alkyl derivatized silica (see **Silica Gel and its Derivatization for Liquid Chromatography**).

RPLC was first developed in the mid- to late-1970s as a direct consequence of needs arising from the shortcomings of normal phase LC. Normal phase LC itself utilizing adsorption chromatography had been an advance on partition chromatography.[1] It might not have preceded RPLC had it not been for the fact that polar materials such as silica and alumina could be produced as porous microparticles while at the time there were no materials available readily to prepare nonpolar porous microparticles. However this situation had to be addressed as the aforementioned shortcomings of normal phase LC became more apparent (see **Silica Gel and its Derivatization for Liquid Chromatography**):

- The silica surface was heterogeneous, containing acidic isolated silanol groups, H-bonded silanol groups, geminal silanol groups, relatively nonpolar Si−O−Si bonds, metal impurity activated silanol groups, ion-exchange $Si-O^-$ sites and adsorbed water; this could give rise to poor efficiency arising from mixed retention mechanisms or at worst very bad peak tailing for basic compounds caused by interaction with the more strongly acidic sites.
- Polar analytes could have very long retention times or, even worse, not be soluble in the mobile phase.

The latter issue was the most telling since much of the momentum for the development of LC was provided by the necessity to analyze drugs in a rapidly expanding pharmaceutical industry. Since drugs must get into the body, which contains a substantial proportion of water, they generally tend to be polar ionizable compounds. Further, they are often presented as salts or in aqueous solutions. Accordingly it became essential that suitable nonpolar stationary phases should be developed in order that polar mobile phases might be used.

In the early days of RPLC the market was dominated by columns packed with Waters' C_{18}-μBondapak, a 10-μm irregular material in which residual silanol groups had not been end-capped (see **Silica Gel and its Derivatization for Liquid Chromatography**). This material enjoyed enduring commercial success but stationary-phase technology soon progressed to the point in the early 1980s that 5-μm spherical end-capped C_{18} materials with a narrow particle size range were the norm. This was still very much the case in the mid-1990s despite a number of subsequent useful developments in the intervening period, including the advent of 3-μm particles, base-deactivated silicas and more stable protected C_{18} materials (sections 3.4 and 4). Similarly there have been many exciting developments in

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

miniaturized LC but in a typical routine quality control laboratory the only concession to saving on solvent use and shortening run times might be the use of a 10-cm or 15-cm column rather than a 25-cm column and only occasionally the use of a 2-mm or 3-mm rather than 4.6-mm inner diameter (ID) column diameter.

A system that would be fairly characteristic of the usual practice of RPLC would therefore be a 150 × 4.6-mm ID stainless steel column packed with a bed of 5-μm spherical end-capped C_{18} porous microparticles with a narrow particle size range using a mobile phase of methanol and an aqueous phosphate buffer. While there are several organic solvents that might be used as alternatives to methanol, most can be ruled out on the grounds of high cost, high toxicity, high viscosity or not being transparent to the detector, usually ultraviolet (UV), being used. Therefore acetonitrile is the only other frequently used organic component of the mobile phase. Tetrahydrofuran (THF) is also used but usually in proportions in the order of 5–20% along with acetonitrile or methanol in order to ''fine tune'' selectivity. Phosphate is a popular buffer because it controls pH well over a wide part (2.5–4.5 and 6.5–7.5) of the pH range between 2.5–7.5 over which silica-based columns are usually considered to be stable. The main disadvantage of its use is that the inorganic salt can precipitate out of the mobile phase if the proportion of the organic component is too high. This is particularly a problem for acetonitrile. Its other disadvantage is that it is not volatile. This is becoming much more of an issue with the increasing use of mass spectrometric detection in LC. Even if an assay is being developed for use with UV detection, mass spectrometry (MS) compatability might still have to be borne in mind since it might become necessary to use MS to identify peaks of unknown identity in the chromatograms obtained. As the instrumentation required to carry out isocratic LC is simpler than that required to carry out gradient LC (see **Gradient Elution Chromatography**) every effort will usually be made to develop isocratic RPLC methods. However for some analyses of complex mixtures in which the compounds present have a wide range of polarities, the use of gradient RPLC may be unavoidable. The determination of structurally related impurities in a drug substance is one such example.

It has already been stated that the desirability of being able to dissolve polar analytes in a polar mobile phase was one of the driving forces for the development of RPLC. This remains one of the main advantages of RPLC. Nonetheless it should not be overlooked that it also has the advantage of being applicable to the analysis of compounds having a very wide range of polarities. The other main advantage is the number of variables that can be used to manipulate selectivity and retention to achieve a desired chromatographic resolution. These advantages together account for the fact that RPLC is so versatile and effective that it is used for a very large proportion of all LC analyses.

The disadvantages of RPLC are few indeed. There are not too many analyte classes for which another mode of chromatography is needed in order to obtain a separation that could not be obtained by RPLC. There are also only a few instances where RPLC is not used for other reasons of a more practical nature. For example wide pore packing materials may be used to carry out RPLC of proteins but another mode of chromatography will frequently be preferred to RPLC because of the danger of the proteins being denatured by the stationary phase or the presence of too high a concentration of the organic component of the mobile phase.

2 THEORY AND RETENTION MECHANISM

Like most other modes of chromatography, retention in RPLC may be described by either a solvent interaction model or a solvent competition model. However it is most commonly interpreted by the application of solvophobic theory[2] which borrows elements from both the solvent interaction and the solvent competition model. The stationary phase is regarded as being saturated with molecules of the organic component, i.e. the most strongly eluting component of the mobile phase. Retention by the stationary phase arises from repulsion of hydrophobic regions of the analyte molecule by the water molecules which ''drives'' the analyte onto the stationary phase or at least into the layer of the organic component adsorbed on its surface (Figure 1). The extent to which the situation resembles the solvent interaction or solvent competition

Figure 1 Retention in RPLC on an alkyl-bonded silica arising from repulsion of nonpolar regions of analyte molecules by the water molecules of the mobile phase.

model might depend on the extent to which this hydrophobic repulsion is moderated by specific analyte–organic solvent or analyte–stationary phase interactions. The frequency with which these are a significant influence is discussed later (sections 3.4 and 3.5).

However, since retention is mainly related to analyte hydrophobicity, the 1-octanol–water partition coefficient ($\log P$), or more particularly $\log P_{app}$ (where P_{app} is the distribution coefficient at a particular pH or apparent partition coefficient; it will be less than P if some of the analyte is ionized at the pH in question) to take into account the degree of ionization at the mobile phase pH, of the analyte can be used either qualitatively or quantitatively to assess how well an analyte will be retained. Similarly in attempting to rationalize the effect experimental variables have on retention it is helpful to think in terms of how a change in the mobile phase will affect the proportion of water molecules in the mobile phase and thereby how it will affect the degree to which the analyte is repelled towards the stationary phase. In the same vein it is helpful to think in terms of how any change of stationary phase might affect the volume of the organic solvent adsorbed on the stationary phase and thereby how its capacity to ''accept'' analyte molecules is affected.

3 EXPERIMENTAL VARIABLES

3.1 Chromatographic Resolution

The whole point of separative methods is to obtain specificity in an analytical method by resolving the analyte from all other detectable components of the sample being analyzed. In RPLC, as with other modes of LC, chromatographic resolution depends on efficiency, retention and selectivity, Equations (1–5):

$$\text{Efficiency, } N = 16\left(\frac{t_r}{w_b}\right)^2 \quad (1)$$

$$\text{Capacity factor, } k' = \frac{t_r - t_0}{t_0} \quad (2)$$

$$\text{Selectivity, } \alpha = \frac{k'_2}{k'_1} \quad (3)$$

$$\text{Resolution, } R_s = \frac{t_{r2} - t_{r1}}{0.5(w_{b2} + w_{b1})} \quad (4)$$

$$R_s = \underbrace{\frac{1}{4}\sqrt{N}}_{\text{efficiency factor}} \cdot \underbrace{\left(\frac{\alpha - 1}{\alpha}\right.}_{\text{selectivity factor}} \cdot \underbrace{\left(\frac{k'_1}{k'_1 + 1}\right.}_{\text{retention factor}} \quad (5)$$

where t_{rx} is the retention time for peak x (r is peak number, e.g. 0 for unretained, 1 for first, 2 for second etc.), t_0 is the retention time for an unretained analyte and w_{bx} is the baseline width for peak x; all of these must be measured in the same units.

Given the general use of 5-μm particles, for good reasons, for example the practical problems associated with the use of particles with lower diameter than this and the fact that there is a square root dependency of resolution on efficiency (Equation 5), means that there is less incentive to overcome these practical problems, and column efficiency is not often used as a variable to improve resolution. Occasionally a chromatographic method may involve operation at elevated temperature, with faster mass transfer resulting in improved efficiency. However the exploitation of elevated temperature in RPLC is more likely to involve simply thermostatting at 5 °C or more above ambient temperature in order to allow strict control of temperature for reproducible chromatography.

Most of the variables in RPLC affect retention but changes in retention have limited value in improving resolution because (i) an increase in run time is not desirable under normal circumstances, (ii) above $k' \sim 4$ increases in retention have limited effectiveness in improving resolution (Figure 2), and (iii) most importantly, most of the variables which change the retention of one sample component will change the retention of all the other components in the same direction (section 3.3). Having said this, it is apparent from Figure 2 that for analytes with k' in the range 0–2, an increase in k' will be highly effective in bringing about an improvement in resolution.

By a process of elimination it should be apparent that improving selectivity is the most useful means of improving resolution and this is indeed the case (Figure 3). The fact that increasing selectivity is not so effective for increasing resolution when selectivity is already greater than ~2 is of little consequence

Figure 2 Variation of retention factor, and therefore resolution, since retention factor $k'/(k' + 1)$ is proportional to R_s.

Figure 3 Variation of selectivity factor, and therefore resolution, with selectivity. $(\alpha - 1)/\alpha$ is proportional to R_s.

because in this range separations would be very easy to achieve in any case. It has already been stated that most of the variables which change the retention of one sample component will change the retention of all the other components in the same direction. Clearly, to improve selectivity it would be best to use an experimental variable that gave rise to increases in retention for some analytes and decreases in retention for others. This is why the use of changes in mobile phase pH is so important in RPLC method development.

3.2 Selectivity Manipulation Using Mobile Phase pH

pH control is very important in RPLC of ionizable compounds, Equation (6) for acids and Equation (7) for bases:

Acids

$$\underset{\text{low pH}}{\text{RH}} \Longleftrightarrow \underset{\text{high pH}}{\text{R}^- + \text{H}^+} \qquad (6)$$

(sulfonic acids, carboxylic acids, phenols, coumarins, sulfonamides, barbiturates, β-diketones, etc.)

Bases

$$\underset{\text{low pH}}{\text{RH}^+} \Longleftrightarrow \underset{\text{high pH}}{\text{R} + \text{H}^+} \qquad (7)$$

(amines)

Irrespective of retention and selectivity issues, it is important that the mobile phase pH is such that an ionizable analyte is either fully ionized or fully un-ionized. For anything in between this situation, if the ionization/deionization rates are not rapid on the chromatographic timescale then chromatographic efficiency will be reduced, possibly accompanied by the development of peak asymmetry. Even if the equilibrium is rapidly reversible, problems might arise. A slight change in the preparation of the mobile phase might introduce a slight change in pH which would bring about a slight change in the position of the equilibrium and thereby a shift in retention. In other words an analytical method based on such chromatography would not be robust.

The decision on whether the ionizable analyte should be chromatographed in its fully ionized form or its fully un-ionized form depends on whether it is required for the analyte to be well retained or otherwise. Clearly the ionized form, being charged, will be the more polar form (Equations 6 and 7). Being more polar it will be less repelled by water molecules and therefore less well retained in RPLC. Accordingly if it is required to reduce the retention of an acid, the mobile phase pH must be increased. Similarly if it is required to reduce the retention of a base, the mobile phase pH must be decreased. The fact that a pH change will affect the retention of an acid and a base in the opposite direction is the reason why it is the most important variable in RPLC method development in the sense that it is able to bring about a change in selectivity.

It is necessary then in RPLC method development to be aware of the pH values at which an analyte will be fully ionized or un-ionized. The degree of ionization of an ionizable analyte at a particular pH may be determined by the well-known Henderson–Hasselbach equation, Equations (8) and (9):

$$\%\ \text{Ionized acid} = \frac{100}{1 + \textit{anti}\log(\text{p}K_a - \text{pH})} \qquad (8)$$

$$\%\ \text{Ionized base} = \frac{100}{1 + \textit{anti}\log(\text{pH} - \text{p}K_a)} \qquad (9)$$

This can be simplified for the situation when the analyte is 50% ionized and so on for 90%, 99%, to develop a so-called ''rule of thumb'', see Table 1.

Therefore for an ionizable analyte to be fully ionized or fully un-ionized the mobile phase pH must be at least three pH units higher or lower than the pK_a of the analyte. While the pK_a of the analyte may be measured, there is a need to know the pK_a of all the other sample components because they will have to be resolved from the analyte. As it is impractical to carry out pK_a measurements for all sample components, it is vital in RPLC for the analyst to be able to recognise functional groups in an analyte and to be aware of their likely pK_a values. This is very much the case, for example, in the analysis of drugs. As has already been stated (section 1), compounds of pharmaceutical interest are usually polar and ionizable.

Table 1 Rule of thumb for ionization of acids and bases[a]

pH	% Ionized[d]	
Acids[b] (e.g. CH_3CO_2H, $pK_a = 4.8$)		
1.8	0.1	↑OH ↑pH ↑% ionized
2.8	1	
3.8	10	$CH_3COOH + OH \longrightarrow CH_3COO + H_2$
4.8	50	
5.8	90	
6.8	99	
7.8	99.9	
Bases[c] (e.g. $H_2N-CH_2-CH_2OH$, pK_a $(NH_3^+) = 9.4$)		
6.4	99.9	
7.4	99	↑H^+ ↓pH ↑% ionized
8.4	90	
9.4	50	$H_2N-CH_2-CH_2OH + H_3O^+ \longrightarrow H_3N^+-CH_2-CH_2OH + H_2O$
10.4	10	
11.4	1	
12.4	0.1	

[a] Adapted from lecture handout. C.J. Edwards, University of Sunderland.
[b] For almost complete ionization, the pH of the environment should be at least three units above the pK_a of the acid.
[c] For almost complete ionization, the pH of the environment should be at least three units below the pK_a of the conjugate acid of the base.
[d] The values for percent ionization shown above are only approximately accurate. Values may be calculated using the Henderson–Hasselbach equation.

In fact they can often contain more than one acidic or basic functional group. Illustrations of the types of functional group found in some common drugs are shown in structures **(1)** to **(8)**.

3.3 Control of Retention

While the manipulation of pH is invaluable with respect to improving selectivity between ionized and un-ionized analytes, the role of other experimental variables in changing retention should not to be underestimated. As has been observed (Figure 2), increasing retention is very effective for increasing resolution when $k' < 2$. At higher retention, increasing retention is a less effective means of improving resolution and in any case it would not be advisable to go on increasing analysis time when it is already excessive.

The effect on k' of changing various experimental variables is shown in Table 2. These effects can be rationalized by the solvophobic theory. For example by increasing the proportion of methanol in the mobile phase or switching from methanol to acetonitrile the mobile phase is made less polar. Being more hydrophobic it is less likely to give rise to repulsion of a hydrophobic region

Table 2 Effect on k′ of experimental variables in RPLC

Variable	Acid	Base	Neutral
pH 2.5 → 7.5	↓	↑	little effect
% methanol ↑	↓	↓	↓
$C_{18} \rightarrow C_8 \rightarrow C_2$	↓	↓	↓
Ionic strength ↑	↑	↑	↑
Methanol → acetonitrile → THF	↓	↓	↓
Add DMOA	↑	slight ↓	little effect
Column strength ↑	no effect	no effect	no effect
Flow rate ↑	no effect	no effect	no effect

DMOA (*N*,*N*-dimethyloctylamine) is a ''masking agent'' introduced into the mobile phase at levels of ~0.0005 M to prevent the interactions between basic analytes and residual silanol groups on the stationary phase which lead to peak tailing.

of the analyte and ''drive'' it onto the stationary phase. Hence the mobile phase is more strongly eluting and k′ is reduced. This holds so long as there is a ''pure'' reversed-phase retention mechanism based on hydrophobicity and there are no specific analyte–solvent interactions. Methanol can take part in hydrogen-bonding interactions, acetonitrile can take part in dipole–dipole interactions and THF can act as an electron pair donor. If such interactions between solvent and analyte take place they will hold up the analyte in the mobile phase more than would be the case and hence give rise to a reduced retention time.

It is perhaps less clear on the basis of solvophobic theory why alklyl-bonded silica phases with longer alkyl chains are more retentive. The greater the ''carbon loading'' of the stationary phase the greater will be its capacity at saturation for the organic component of the mobile phase. Effectively then the stationary phase has a greater ''volume'' and is therefore more retentive.

The effect of masking agents such as DMOA (see **Silica Gel and its Derivatization for Liquid Chromatography**) on retention has been less of a concern because they are being used less with the increasing use of base-deactivated silaceous reversed-phase packing materials. However it remains an issue since many methods that were developed years ago are still in use. The interactions of basic analytes with residual silanols that the masking agent is designed to block contribute to the overall degree of retention. Therefore when the blocking takes place, k′ is reduced. Generally silanol interactions do not contribute significantly to the retention of neutral and acidic analytes. However, acidic analytes in their ionized form may enter into a hydrophobic ion-pair with net zero charge with the masking agent and hence be more retained.

While changes in flow rate and column length affect retention time they clearly do not affect k, as the elution time of an unretained analyte would be changed in the same way. Any changes to resolution that they bring about will arise from their effect on column efficiency.

3.4 Stationary Phase Selectivity

As mentioned already in the context of the use of masking agents and the occurrence of solvent–analyte interactions, the retention mechanism in RPLC will not always be exclusively based on hydrophobicity. The most common additional contribution to retention from stationary phases is that from the interaction of basic analytes with residual silanol groups on the stationary phase, this being more of a problem for more acidic isolated silanol groups or those activated by the presence of metallic impurities than for silanols which are H-bonded to neighboring silanols. While these interactions affect peak shape and retention of basic analytes they would not have a profound affect on the selectivity exhibited towards a series of basic analytes. The same may be said for stationary phase specific interactions exhibited by functional groups (e.g. cyano-, phenyl-, diol, nitro-) present in medium polarity RPLC stationary phases. Studies with a wide range of model analytes have suggested that retention orders correlate fairly well with those found on alkyl-bonded silicas.[3]

Retention in the few stationary phases that are not silica-based is also dependent on hydrophobicity. This is especially the case for the styrene–divinylbenzene copolymer (PRP-1) (Scheme 1). There appear to be no specific interreactions with the aromatic rings on the stationary phase surface and the degree of correlation between retention and hydrophobicity is such that log k′ values may be used as a measure of analyte partition coefficients.

Scheme 1 Preparation of PRP-1.

Another nonsilaceous packing material for RPLC is the porous graphitic carbon phase, Hypercarb®. Like PRP-1, Hypercarb® can be used at extremes of pH and is more retentive than octadecylsilyl silicas. In fact it is much more retentive even than PRP-1 and this is a property that may be usefully exploited. A good illustration of this is the use of Hypercarb® in microbore LC columns. One of the advantages of microbore LC is that it may be used to obtain increased mass sensitivity. However gains in this direction are compromised by extra-column band-broadening effects arising in particular from the injection volume. As Hypercarb® is so retentive it is an easy matter to find a weakly eluting solvent for the sample solution so that when large volumes of sample solution are injected onto the column an on-column sample focusing effect takes place.

While the fact that Hypercarb® is highly retentive and may be used at extremes of pH is of interest, what really sets this material apart is its unique selectivity. Hydrophobicity has an influence on retention but there is a strong contribution from π-stacking effects and there is often strong retention of rigid planar analyte molecules which are able to interact strongly with the flat planar graphite surface (Figure 4). Accordingly Hypercarb® is the only material used in RPLC that has sufficiently different selectivity from that of alkyl-bonded silicas for it to be claimed to have ''orthogonal'' selectivity from such phases.

3.5 Mobile Phase Optimization

As retention in RPLC is so dependent on hydrophobicity of the analyte, mobile phase and stationary phase, method development in RPLC ought to be fairly simple with retention times of analytes being fairly easy to predict. The issue of course is complicated by the contributions to retention of specific solvent and stationary phase interactions which are difficult to predict a priori. Therefore, rather than using expert systems which use information on analyte, stationary phase and mobile phase properties, it is much more common to choose a column likely to be suitable for the analyte and to carry out computer-aided automated mobile phase optimization in which predictions are based on a few initial experiments with the mobile phase conditions then being refined. One of the most popular packages used for RPLC method development is DryLab in which isocratic and gradient conditions are predicted on the basis of just two initial experiments which are usually gradient runs. This allows the analyst quickly to arrive at suitable mobile phase conditions under which the analytes have the desired retention times. There is a range of more sophisticated software packages available which are designed to work in conjunction with a specific manufacturer's instrumentation to allow totally unattended fine tuning of the separation.[4]

Figure 4 Structure (a), surface cross-section (b) and plan-view (c) of the porous graphitic carbon stationary phase, Hypercarb®.

4 PERSPECTIVE AND FUTURE DEVELOPMENTS

Despite the availability of other modes of LC and alternative techniques such as capillary electrophoresis and capillary electrochromatography, RPLC will continue to be the most frequently used means of carrying out a separative method for the foreseeable future. It is versatile, provides adequate resolution and convenient conditions for the vast majority of applications and, most importantly, because there are vast sums of money invested into the use of RPLC, it will not be replaced until the unlikely event of a new LC mode or alternative technique coming along which is significantly better than RPLC across the board.

Developments in new stationary phases will continue but already much has been done to exploit materials other than silica and to produce silica-based phases which are usable over a wider pH range and/or may be made more reproducible and/or give much reduced peak tailing with basic analytes. As for other modes of LC there will be further moves in RPLC towards the use of columns with reduced dimensions. This is because economic and environmental considerations are now more important. Also, with the increasing use of mass spectrometric detection for RPLC there is less need for complete resolution of all peaks so that it is possible to use shorter columns with faster flow rates for increased sample throughput. One of the main advantages of RPLC is that it may be used for a wide range of analyte polarities. However this often leads to the necessity for solvent gradient methods when the sample is a complex mixture containing analytes with very different polarities. This requires more sophisticated instrumentation and usually involves long analysis times even not allowing for the time required for the column to be reconditioned with the starting mobile phase. The elimination of such lengthy procedures is one of the few remaining research targets in RPLC.

ABBREVIATIONS AND ACRONYMS

DMOA	*N*,*N*-Dimethyloctylamine
ID	Inner Diameter
LC	Liquid Chromatography
MS	Mass Spectrometry
PRP-1	Styrene–Divinylbenzene Copolymer
RPLC	Reversed-phase Liquid Chromatography

In this article, we review the preparation and use of silica and its derivatives in liquid chromatography (LC). First, the properties of silica that are important for its application in LC are examined, then bonded phases and coated phases based on silica are considered. The current state-of-the-art of the preparation of bonded phases and coated phases is surveyed, and the properties that are relevant for the chromatographer are discussed. Owing to the popularity of reversed-phase liquid chromatography (RPLC), most of the emphasis is placed on phases used in this technique, but other chromatographic techniques are not ignored. A detailed characterization of reversed-phase packings is provided.

1 INTRODUCTION

Bonded phases based on silica gel as well as other silica derivatives constitute the most widely used stationary phases in high-performance liquid chromatography (HPLC). On one hand, this is due to the superior hardness of silica compared with organic gels, which enables the use of the high pressures required to achieve high resolving power at short analysis times. On the other hand, the ability to modify the surface of silica via silanization has contributed significantly to its widespread applicability. While the chemical stability of zirconia or titania is significantly better than that of silica, the surface chemistry of these oxides is more complicated and cannot be manipulated as easily as the surface chemistry of silica. Therefore, the true secret of the success of silica lies in the silanization chemistry.

In this article, the physical and chemical properties of silicas used as sorbents in HPLC will be reviewed first. This discussion includes a brief description of the newer technologies such as nonporous particles and continuous rods. Then silica-based bonded phases will be described in substantial detail: preparation techniques, properties of the bonded phases and general characterization techniques, and the properties and use of specific bonded phases. Owing to the widespread use of reversed-phase chromatography, most of this section is dedicated to C_{18} and C_8 bonded phases; however, we will not neglect specific topics such as special phases designed for carbohydrate separations or protein separations. The final section is dedicated to phases that are coated onto silica. These phases may or may not be attached to the silica surface. We will review the preparation techniques as well as the properties of these phases. It should be noted that some of the stationary phases of this type can also be prepared on other inorganic carriers, but a wider discussion is outside the scope of this article.

2 PROPERTIES OF SILICA

What are the properties of silica that make it desirable for use as a sorbent in HPLC? Chromatographic retention is proportional to the ratio of accessible surface area to packed bed volume. In addition, the amount of analyte that can be injected onto a column is also a function of the surface area in a column. Since the analysis should be insensitive to the amount injected onto a column, the surface area of a packing should be maximized. To achieve a maximum ratio of surface area to volume, the packing should be porous. However, the surface needs to be accessible to the analytes of interest, which puts a lower limit on the pore size and an upper limit on the specific surface area of a packing. The freedom in the manipulation of pore size and surface area is one of the strengths of silica.

In contrast to sorbents based on an organic backbone, silica does not swell nor shrink depending on the solvent in

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

which it is used. Physical properties such as pore volume, pore size distribution and surface area are permanent properties of the packing. Similarly, the permeability of a packed bed is independent of the solvent used. Both effects represent significant advantages in the solvent compatibility of silica-based packings compared with organic polymeric packings. The hardness of the packings also allows the use of higher pressures and smaller particle sizes than are possible with organic polymeric packings.

The third distinguishing property of silica is the ease of modification of the surface using silanization techniques. Silanization allows the design of ''reversed'' phases and many other bonded phases that modify the properties of the native silica substantially and therefore enable specific separation techniques that are not possible with other packings. Most of the discussion in this article is dedicated to the description of the surface modification of silica.

In the following paragraphs, the physical properties of silica and packed beds are first discussed in more detail. Then the chemical properties of silica are examined.

2.1 Preparation of Porous Silicas

In order to frame this discussion, we will start with a brief review of the preparation of porous silica.[1] The common starting point in the preparation is a silicic acid monomer, such as sodium silicate or one of the silicic acid esters, such as tetramethoxysilane. These monomers are polymerized to a specific molecular weight or size. This prepolymerized silica, which may be in the form of a sol, is then further agglomerated to form the final particles. The agglomeration is carried out in the presence of porogens, which are additives that are used to influence the specific pore volume and, together with the size distribution of the prepolymerized sol, the pore size distribution of the silica. In all modern preparation techniques for HPLC-grade silica, spherical particles are generated in this process. The most commonly used technique for the preparation of the silica particles is suspension polymerization, but a spray drying process can be employed as well. The type and purity of the raw materials significantly influence the properties of the chromatographic sorbent. This will be discussed in more detail in section 2.3 which discusses chemical properties of silica, and section 3.5.2 which covers the chromatographic tests for the properties of reversed-phase bonded phases.

The retentive properties of a silica for specific analytes depend on the access of the analytes to its surface and therefore on its pore size distribution. The pore size distribution of a silica prepared in the manner described above depends on the size distribution of the primary silica sol and the specific pore volume. If one wants to change the average pore size of a packing, two techniques are available. The first technique is manipulation of the average size of the sol before preparation of the silica particle. The second is the use of an Ostwald ripening technique to increase the size of the structural units that form the backbone of the silica particle. This second technique is employed after preparation of the particle and is mostly utilized in the production of silica gels with a large pore size, which are commonly used for the chromatography of high-molecular-weight compounds such as polymers and biopolymers. In this technique the silica is subjected to elevated temperature and pressure in the presence of water in an autoclave to achieve the desired pore size distribution. Under these conditions, both the structure of the silica backbone and the pores grow in size. Additionally, if carried out properly, the pore volume remains largely unaffected. Silicas prepared by both techniques can be distinguished easily microscopically (Figures 1 and 2).

2.2 Physical Properties of Silicas

2.2.1 Pore Size, Pore Volume, Surface Area

The pore size distribution, pore volume and surface area are the physical characteristics of a silica that are responsible for its retention properties. Porous silicas used for the chromatography of small molecules have an average pore size of around 10 nm (commonly 5 nm to 15 nm) and a specific surface area between $100\,m^2\,g^{-1}$ and $400\,m^2\,g^{-1}$. Silicas with an average pore size smaller than about 5 nm exhibit restriction to mass transfer in the pores for typical analytes. As a result, chromatographic peaks are broader than they should be. Silicas with a

Figure 2 Silica prepared using Ostwald ripening for pore enlargement. The structure reminiscent of corals is typical for a pore-enlarged silica. Material: Nucleosil® 4000–7 (Macherey-Nagel, Germany).

significantly larger pore size have a smaller surface area and therefore less retention for typical analytes. However, as the molecular weight of the analytes increases, the pore size of the most appropriate packing increases as well. The chromatography of proteins is commonly carried out using silicas with an average pore size of 30 nm or more.

The *specific* surface area and the *specific* pore volume are the respective values normalized per gram of packing. They are commonly reported in the manufacturers' literature. While the surface area of a packing is responsible for the retention, it should not be assumed that the retentivity of a silica is proportional to the surface area alone. It should be remembered that the retentivity of a silica is determined by the phase ratio of a packing, which is the ratio of surface area to fluid volume in a packed bed. The phase ratio β can be calculated by Equation (1):

$$\beta = (1 - \varepsilon_i)\frac{A_{sp}}{V_{sp} + (1/\rho_{sk})} \quad (1)$$

[a] The source of this information is the column manufacturer's literature. No guarantee of the accuracy of the information can be made.

where ε_i is the interstitial porosity of the packed bed, with a typical value of 0.4 for spherical particles. A_{sp} is the specific surface area of the packing and V_{sp} is its specific pore volume. ρ_{sk} is the skeletal density of the packing, which is 2.2 g cm^{-3} for silica. As we can see, silicas with large specific surface areas and large specific pore volumes have a similar phase ratio, and therefore similar retentivity, to silicas with small specific surface areas and small specific pore volumes. To obtain a true impression of the retentivity of a packing, it is therefore important to calculate the phase ratio rather than considering the specific surface area of a packing alone. This has been done in Table 1 for a range of commercial packings, for which the relevant information is available.

The three parameters, average pore size d_{po}, pore volume V_{sp} and surface area A_{sp} are interdependent: if two are fixed, the third one is determined as well (p. 41 of Unger[1]). This can be expressed by the formula in Equation (2):

$$A_{sp} \approx 3\frac{V_{sp}}{d_{po}}. \quad (2)$$

This approximate formula can be used to estimate the average pore size of a packing. This is quite useful, since there are no commonly accepted conventions for the determination of the average pore size.

The specific pore volume of a silica is the key factor that determines the hardness or strength of a silica. Packings with a small pore volume are stronger than packings with a large pore volume. However, all silicas with a specific pore volume of up to about 1 mL g^{-1} are quite suitable for HPLC applications and can be subjected to column inlet pressures in excess of 40 MPa, which is the common pressure limit of most HPLC instrumentation.[2]

2.2.2 *Particle Size*

The particle size of a packing determines the chromatographic efficiency and the backpressure of columns packed with these particles. The most commonly used particle size is 5 µm for analytical separations, but 10 µm particles are still employed, while the application of columns packed with 3-µm particles is steadily increasing. Columns packed with fully porous particles down to a particle size of 1.5 µm are commercially available, but their usefulness has not yet been sufficiently explored. For preparative applications, larger particle sizes are frequently employed owing to the pressure limitation of the chromatography instrument on the one hand and the lower demand on the separation power of the column on the other.

Pressure limitations also play a role in the use of analytical columns. Commonly, the preferred operating range is at pressures less than 20 MPa, but most columns are stable at pressures exceeding twice this value. The pressure limitations are related to the equipment rather than the columns. The pressure needed to use a column at a particular flow rate increases with increasing column length. Also, at a given column length, the pressure is inversely proportional to the square of the particle size. This puts a general limit on the ratio of column length to particle size.

It is worthwhile exploring the properties of column length and particle size a little further. Generally[2] the maximum plate count of a column depends simply on the ratio of column length to particle size. Similarly, the shortest analysis time that can be reached at a given pressure limit is also simply a function of the ratio of column length to particle size. Columns with a larger length to particle size ratio achieve a higher plate count, but are slower. Columns with a smaller length to particle size ratio are faster, but have a lower plate count maximum. The particle size, together with the mobile phase viscosity and the molecular weight of the analyte, determines the analysis time at which the optimum column performance is achieved. It occurs at a slower analysis time for larger particles than for smaller particles. The analysis time at which an equal plate count maximum is achieved decreases with the square of the particle size at a constant length to particle size ratio. However, the pressure limitations of the instrumentation set a limit to both the plate count and the speed of a particular analysis, even if this optimization process is followed. An additional limit to column design has been pointed out by Halász and colleagues.[3] The pressure needed to pump the mobile phase through the column generates a significant amount of heat, which measurably affects retention for particles of 3 µm or less.

Nearly all HPLC packings have a fairly wide particle size distribution, most commonly extending to ±25% around the mean. In addition, what is given as the average particle size depends on the measurement technique[2] and no standard technique has been established. Therefore the ''5-µm'' particles of one manufacturer are not necessarily identical to the ''5-µm'' particles of another. However, since the backpressure of a column depends on the particle size of the packing, this observation can be turned around and the average particle size d_p can be determined from the backpressure Δp of a column.[3] The procedure requires knowledge of the flow rate F, the viscosity of the mobile phase η and the column dimensions, (Equation 3):

$$d_p = \sqrt{1000\frac{F\eta L}{\pi r^2 \Delta p}} \quad (3)$$

This very practical procedure puts the determination of the particle size in the hands of the HPLC user.

Figure 3 Particle size distribution of a modern HPLC packing. The characteristic values are the center of the distribution at the 50% point and the ratio of the 90% point to the 10% point, which is a measure of the width of the distribution.

Both the efficiency of a column and the column backpressure depend on the width of the particle size distribution. The permeability of a column, and thus its backpressure, depends cleanly on the square of the population-average particle size. However, column performance as measured by the *C*-term of the van Deemter equation,[4] seems to depend on the volume-average particle size.[2] Since the difference between population-average particle size and volume-average particle size decreases with the width of the distribution, narrower particle size distributions are preferred over broader distributions.

The value commonly used for an assessment of the width of a particle size distribution is the ratio of the 90% point to the 10% point, often of the volumetric distribution (Figure 3). For today's high-quality packings, this value may be around 1.5 or smaller.

2.2.3 Porous Versus Nonporous Particles

Nonporous particles with a small particle size (down to 1.5 μm) have now become commercially available. Due to the low permeability of packed beds prepared from such a small particle size, the columns used are quite short. Fast analyses can still be achieved with reasonable column performance, albeit at high backpressure. However, a major drawback of nonporous particles compared with fully porous particles is the significantly lower surface area per column volume. The amount that can be injected on a column without peak distortion depends on the surface area of the packing. For small molecules, the mass loadability of a packed bed prepared from nonporous particles is over three orders of magnitude lower than the loadability of the same bed prepared from fully porous particles. In addition, significant differences in the mobile-phase composition are required to obtain the same retention with nonporous and with porous particles. For the analysis of small molecules, the use of nonporous particles does not provide any benefits compared with porous particles.

However, the situation changes when the retention chromatography of macromolecules is considered, such as proteins and nucleic acids. For unrestricted access of molecules of a very large molecular weight to the surface of the packing, the pore size of the packing needs to be very large. Under these circumstances, the surface area available for interaction is not much larger for a fully porous packing and a nonporous packing, and quite good performances have been achieved[5–9] using nonporous particles. For analytical separations of macromolecules, the use of nonporous particles makes sense. A review by Lee[9] deals with the separation of proteins using nonporous sorbents.

2.2.4 Continuous Structures

The newest development in the design of separation devices are continuous rod columns.[10–12] In this case, the chromatographic bed consists of a continuous porous structure with a dual pore size, containing micropores that provide the surface for chromatographic retention and macropores that provide the flow channels, like the interstitial space in a packed bed. The advantage of such a continuous structure lies in the fact that the size of the macropores can to some degree be designed independently of the size of the structural units that contain the micropores. Consequently, structures can be designed that provide a higher performance at a given permeability or a higher permeability at a given performance than packed beds can provide.

At the time of writing (1998), the practical limitations of continuous rod columns are not known, although just as in a packed bed, the structural uniformity of the rod plays a significant role in its performance. For bonded phases, uniform derivatization of the chromatographic surface needs to be achieved. While the capabilities and limitations of packed bed technology are reasonably well understood, it is not clear if the continuous rod technology gives similar freedom in the design and manufacturing of chromatographic beds of widely varying aspect ratios and widely varying surface chemistry.

To evaluate continuous rod structures (or other chromatographic devices) and compare them to packed beds, we can follow the thought process outlined by Neue on page 73 of his book.[2] The chromatographic structure is treated as a black box, whose internal makeup is unknown. From the permeability of the device, the particle size equivalent of a packed bed can be calculated (Equation 3). The height equivalent to a theoretical plate

(HETP) is then measured as a function of the linear velocity. Then, the particle size equivalent is used to create the reduced plate height and the reduced velocity, just as if the device were a packed bed. In this way, all chromatographic devices are compared with each other using exactly the same framework: separation power, speed of analysis and pressure.

2.3 Chemical Properties

The chemical properties of silica vary somewhat with the preparation technique and the purity of the raw materials used in the preparation.[1] Nevertheless, a range of general statements can be made that are universally applicable.

The surface of a chromatographic silica is covered with silanol groups, which are responsible for the polar adsorption properties of the silica, and with siloxane bridges. Several different types of silanol can be distinguished, structures **(1)** and **(2)**: single or lone silanols, bridged or vicinal silanols which emerge from neighboring silicon atoms and are joined by a hydrogen bridge and geminal silanols, which are attached to the same silicon atom. Silanols are weakly acidic adsorption sites. They are also the sites at which further chemical modification of the silica is initiated.

(1) **(2)**

A fully hydroxylated silica contains about $8\,\mu mol\,m^{-2}$ of silanols, or about five silanol groups per square nanometer. In water, the silanols dissociate at pH values higher than about 3. Therefore, silica is a weak cation exchanger. Consequently, the surface of a silica may contain cations unless it has been treated with an acid. If waterglass (sodium silicate) is used as a raw material, the surface of the silica may be occupied by sodium ions. Cations on the surface of the silica can be removed fairly easily by treatment with acids. However, if the cations are incorporated in the matrix, they can not be removed. Apart from sodium, aluminum or iron are common contaminants of classical silicas. The metal ions in the silica matrix affect the activity, or better said the acidity, of the surface silanols. This in turn can lead to undesirable interactions with analytes, especially in the chromatography of analytes with basic functional groups in reversed-phase chromatography. Therefore, newer high-purity silicas were developed in the late 1980s and early 1990s, based on organic silanes such as tetramethoxysilane as raw materials. Reversed-phase packings based on high-purity silicas have rapidly gained acceptance owing to their superior chromatographic performance with basic analytes. An excellent review of the influence of silica structure and impurities has been published by Cox.[13]

When silica is heated, neighboring silanols condense and form siloxane bridges, leaving behind lone silanols. At temperatures higher than about 800 °C, most of the silanols have been removed and the structure of the silica starts to collapse, resulting ultimately in sintering of the particles. At lower temperatures, the siloxane formation is reversible and silica treated at elevated temperature can be rehydroxylated. The preparation of many silicas requires the addition of an organic polymer to influence the pore volume and this polymer is often removed by treatment at elevated temperature. Since the high-temperature treatment removes silanols, rehydroxylation of the silica surface is an important step in the preparation of many silicas. The activity of a silica depends on the details of its temperature history.

3 BONDED PHASES

Bonded phases can be broadly grouped into two categories, nonpolar bonded phases used for reversed-phase applications and bonded phases with polar functional groups that can be used in normal-phase chromatography, hydrophilic-interaction chromatography, size-exclusion chromatography, or ion-exchange chromatography. Owing to the popularity of reversed-phase chromatography, most of the work on the preparation and characterization of bonded phases has focused on this class of packings. In this section, we will first concentrate on the different approaches used to derivatize silica via silanization techniques. Classical techniques as well as some of the newer techniques will be discussed. Then the properties of specific bonded phases, their characterization and their use will be examined.

3.1 Derivatization Techniques

The preparation of a bonded phase commonly starts with a clean fully hydroxylated silica. Silanization of the surface can be carried out with chlorosilanes, alkoxysilanes, aminosilanes or other reactive silanes. The classical approach to the preparation of reversed-phase packings uses chlorosilanes in the presence of a scavenger of the hydrochloric acid by-product (Scheme 1). Inexpensive organic bases such as pyridinium or triethylamine are commonly used to remove the hydrochloric acid.

Bonded phases with polar functional groups are usually prepared using alkoxysilanes. Two approaches towards this reaction have been reported in the literature. In

Scheme 1

the first approach (Scheme 2), the alkoxysilane is reacted directly with the silica surface in a hydrophobic solvent such as toluene.[14] The side product of this reaction is an alcohol, which can subsequently react with surface silanols to form an alkoxy-derivatized silica. Therefore, the alcohol needs to be removed from the reaction mixture.

Scheme 2

The second approach towards polar bonded phases is the derivatization of the silica in an aqueous medium. In this approach, the silane polymerizes initially and the reaction with the surface occurs in a secondary step. This is shown schematically below; the secondary step is simplified as the formation of a trisilanol and its condensation with the silica surface (Scheme 3):

Scheme 3

Despite the complexity of this reaction, good results have been obtained with it. For example, the reaction of silica with glycidoxypropylsilane results in materials that are suitable for aqueous size-exclusion chromatography owing to a low level of interaction with analytes in aqueous mobile phases.

Other derivatization techniques have been reported as well. A high-temperature derivatization with hexamethylcyclotrisiloxane[15] has been patented. The quality of the surface modification appears to be quite good. Also, other reactive silanes can be used.

The level of the surface derivatization can be assessed through elemental analysis. Manufacturers of stationary phases often report typical values for the carbon content of silica-based bonded phases. However, a better picture of the nature of the surface is obtained when the surface coverage which expresses the molar amount of ligand attached to the surface per unit surface area, is calculated. The surface coverage χ for a monofunctional silane is calculated in Equation (4):

$$\chi = \frac{\%C}{100A_{sp}n_c12\left(1 - \frac{\%C}{100}\frac{MW-1}{n_c12}\right.} \qquad (4)$$

where $\%C$ is the carbon content obtained from elemental analysis, A_{sp} is the specific surface area of the underivatized silica, MW is the molecular weight of the ligand and n_C is the number of carbon atoms in the bonded phase molecule. Equation (4) takes into account the weight gain of the sample due to the incorporation of the bonded phase. For bi- and trifunctional silanes, the weight gain correction is not quite as straightforward. Probably the best approach is to assume that the bonded phase is attached to the surface via two Si−O bonds or to measure the actual distribution using ^{29}Si-CP/MAS/NMR (cross-polarization/magic angle spinning/nuclear magnetic resonance).

The silane used for the derivatization can be a monofunctional **(3)**, difunctional **(4)** and **(5)** or trifunctional silane **(6)** and **(7)**. Depending on this characteristic, the silane can bond to the surface with one or two chemical bonds. The formation of a triple bond with the surface can be excluded for steric reasons. However, with multifunctional silanes the formation of siloxane bridges to neighboring ligands is possible as well.

When a monofunctional silane is reacted with the silica surface, the surface coverage is limited by steric hindrance. Only less than about 4 μmol m^{-2} of a monofunctional silane fit onto the surface.[14] For difunctional silanes, a larger surface coverage can be achieved. However, it seems that the removal of surface silanols is still incomplete.[16–18] For every silane that binds to the surface, only 1.5 silanols are on the average removed from the surface. With trifunctional silanes, the number of silanols consumed per bound silane is limited to two anyway; therefore, every trifunctional ligand that is attached to the surface generates at least one new silanol group.

(8)

While an additional removal of silanols should not be impossible, the literature information is inconclusive.

Further removal of silanols from reversed-phase packings after the primary bonding procedure has taken place can be accomplished by a process called ''endcapping''.[1] In this case, an active trimethylsilane is used to bond to silanols that were either formed in the primary reaction (multifunctional silanes) or did not react due to steric hindrance. Commonly, trimethylchlorosilane, hexamethyldisilazane, mixtures of both or other reactive trimethylsilanes have been used.[19–21] Recently, high-temperature endcapping reactions have been explored.[22,23] Generally, the endcapping process is quite effective and the removal of silanols is measurable. However, complete removal of silanols is impossible for steric reasons.[24,25] **(8)** is a schematic representation of the surface of a typical reversed-phase packing, a fully endcapped C_8 bonded phase with a high level of derivatization. Note that there are about as many silanols left on the surface as have been reacted with either the C_8 reagent or the endcapping reagent. Even for highly derivatized packings, ''residual'' silanols contribute to the retention properties of the packing.

3.2 Monofunctional Phases

Monofunctional phases are derived from silanes that can react with the silica surface through one single bond only. Many reversed-phase stationary phases are based on monofunctional silanes. The largest advantage of these phases is the reproducibility of the preparation. When multifunctional silanes are reacted with the silica surface in the presence of small amounts of water, additional silanol groups are created through the hydrolysis of the reactive group. As a consequence, the reaction can proceed further than in the absence of water. This does not occur when monofunctional silanes are reacted with the silica surface. The high reproducibility of the preparation of the stationary phases based on monofunctional silanes has been demonstrated in the literature.[26,27]

A disadvantage of the use of monofunctional silanes is the ease with which the single bond to the surface is cleaved. Especially at pH values below 2, the weakest point of the attachment of the bonded phase is the Si–O–Si linkage. However, the nature of the ligand influences the stability of the bonded phase at low pH. Kirkland et al. have described[28,29] a group of bonded phases that improve this problem: they use ligands with large bulky side chains that sterically protect the point of attachment of the ligand to the surface, **(9)** and **(10)**.

(9)

(10)

The improvement in hydrolytic stability at low pH is excellent compared with simple monofunctional phases with methyl groups as the side chains. However, the larger steric hindrance also results in a lower coverage, exposing more silanols. Therefore, the adsorptive properties of these phases are inferior to densely coated classical phases, especially around neutral pH, leading to tailing for basic analytes.

3.3 Multifunctional Phases

The classical approach towards the preparation of multifunctional phases uses di- and trifunctional silanes that can bond to the surface via multiple bonds. Improvements in hydrolytic stability result at low pH. At high pH, however, the dissolution of the silica itself determines the hydrolytic stability of a phase, and therefore the type of bonded phase plays only a secondary role.

Generally, the reproducibility of the preparation of multifunctional phases is inferior to monofunctional phases and the bonding reactions need to be controlled more closely. A key factor in the preparation of multifunctional phases is the influence of trace amounts of water on the reaction. For chlorosilanes, the presence of water in the reaction medium creates a polymerization reaction, which influences the nature and the amount of ligand attached to the surface. On the other hand, water acts as a catalyst in the reaction of alkoxysilanes with silica and is an important ingredient in the preparation of bonded phases prepared from alkoxysilanes.[16,30]

Most phases designed for applications other than reversed-phase chromatography are based on multifunctional silanes. Typical examples are the propylamino phase or the diol phase. Therefore, we need to realize that the presence of unprotected and unshielded silanols plays a role in the adsorptive properties of these phases. This will be discussed in more detail in the section that deals with specific bonded phases.

An alternative approach to the design of stationary phases has been discussed by Kirkland et al.[28] The ligands that he attached to the surface contain two reactive silanes linked by a short hydrocarbon chain **(11)**:

(11)

It is expected that the hydrolytic stability of such phases is improved over classical bonded phases, if indeed both silicons are attached to the surface. The details of this reaction are still unknown.

Another more recent approach is the attempt to form initially a monolayer of a trifunctional silane on the silica surface followed by bonding this monolayer to the surface.[31,32] However, the chromatographic evaluation of these materials in the literature is only sketchy. An evaluation in our own laboratory[33] demonstrated an excellent chemical stability of the packing, but the silanol activity was very high compared with modern HPLC packings. A key assumption underlying the ''horizontal'' polymerization technique is the flatness of the surface, which is not given for porous packings.

The use of multifunctional silanes allows for a high coating level on the surface. Sander and Wise have shown[34,35] that the relative retention and therefore the resolution of polynuclear aromatic hydrocarbons depends on the density of the C_{18} chains of a reversed-phase packing (Figure 4). Therefore, C_{18} bonded phases with a high coating level based on

Figure 4 Separation of polynuclear aromatic hydrocarbons on C_{18} phases with different coating levels. (a) 6 nm pores, $\alpha_{TBN/BaP} = 1.32$; (b) 10 nm pores, $\alpha_{TBN/BaP} = 1.24$; (c) 15 nm pores, $\alpha_{TBN/BaP} = 0.84$; (d) 30 nm pores, $\alpha_{TBN/BaP} = 0.85$ (BaP, benzo[*a*]pyrene; TBN, 1,2-3,4-5,6-7,8-tetrabenzonaphthalene.) (Reproduced from Sander and Wise, *J. Chromatogr. A*,[34] Copyright (1993) with permission from Elsevier Science.)

trifunctional silanes have found a specific application niche in the environmental analysis of polynuclear hydrocarbons.

Along the same lines, a polymeric C_{30} stationary phase[36] has been developed that is capable of separating the geometric isomers of common carotenoids. Comparisons with traditional C_{18} phases demonstrated the superior resolving power of the C_{30} bonded phase for this class of compounds.[37]

3.4 Other Approaches

There are a few interesting approaches to the design of special stationary phases that have not yet been covered in this discussion. One is the design of immobilized artificial membranes (IAMs),[38–41] consisting of a monolayer of phospholipid covalently bonded to the surface of a silica (Figure 5). The IAM derivatized silica is a chemically stable chromatographic packing that emulates the exterior of a biological cell membrane. The logarithm of the retention factor of drugs measured on an IAM column correlates well with their permeability through Caco-2 cells[42] or their absorption by inverted rat intestine.[43] Therefore, fast chromatographic methods can be used to estimate the drug permeability through biological membranes. Recently, IAM columns have been used for rapid screening of drug–membrane interactions in drug discovery.[44]

Another interesting technology is the use of reversed-phase packings designed with an external hydrophilic surface. These packings, called internal-surface reversed-phase or restricted access packings,[45,46] are designed for the chromatographic analysis of drugs directly from blood plasma. The internal hydrophobic surface on the inside of the pores of the packing is responsible for the retention of drugs and metabolites. However, proteins interact only with the external hydrophilic surface and are excluded from the internal surface owing to their size. The binding of proteins to the external hydrophilic surface is weak and they are eluted without difficulty. On classical reversed-phase packings, proteins would stick to the external surface and rapidly clog the column. Therefore, improved column life is possible with restricted-access packings, but the internal surface can still become contaminated with lower-molecular-weight contaminants that can penetrate the pores.

Figure 5 IAM. The phase designated ^{ether}IAM.PC$^{C10/C3}$ by Ong et al.[38] is shown.

In one approach,[45] a hydrophobic tripeptide is bonded to a diol-derivatized silica with a standard pore size. Subsequently, the peptide is clipped off the external surface of the packing with an enzyme that is unable to penetrate the smaller pores of the packing. Consequently, the external surface becomes hydrophilic, showing little interaction with serum proteins, while the internal surface is responsible for the reversed-phase retention of the smaller analytes. In the second approach,[46] a standard hydrophobic surface is created first via a standard silanization technique. Then, the packing is immersed in an aqueous acid. Surface tension does not permit the penetration of the aqueous acid into the hydrophobic pores, but the coating external to the pores of the packing is cleaved off. In the final step, the external surface is coated with a diol silane to prevent the interaction of proteins with the external surface.

In order to create an analog to lipid membranes for separation with molecular recognition, a comb-shaped bonded phase was devised.[47] The ligand was synthesized by telomerization of 3-thiopropyltrimethoxysilane and octadecylacrylate and subsequently attached to the surface of silica. This bonded phase showed a remarkable temperature dependence of the retention factor and of the relative retention for aromatic hydrocarbons, indicating a phase transition of the immobilized ligand.

3.5 Properties of Bonded Phases

In this section, the specific properties of bonded phases and their use will be examined. Since the largest use of columns is for reversed-phase chromatography, this application area will be discussed first. Included in the discussion is the description of evaluation techniques for reversed-phase packings and the reproducibility of the preparation technique. Then we will discuss normal phase chromatography, followed by a brief review of other application areas.

3.5.1 Phases for Reversed-Phase Chromatography

The most commonly used phase for reversed-phase chromatography is the C_{18} phase, in which an octadecylsilane **(12)** is attached to the silica. This is followed by the closely related C_8 phase which uses an octylsilane **(13)**.

(12)

(13)

The retention of hydrophobic analytes in a given mobile phase is generally larger for a C_{18} phase than for a C_8 phase, and generally proportional to the ratio of the amount of stationary phase to the mobile phase volume, similar to the phase ratio discussed earlier. Therefore, C_{18} phases with a low surface coverage may exhibit retention properties similar to highly coated C_8 phases. For more polar analytes, the situation is more complicated: polar analytes may penetrate the bonded-phase layer only partially and therefore interact with only part of the bonded phase.[48,49] In such a case, the retentivity of a C_{18} and a C_8 phase may be very similar. Conversely, polar, especially basic analytes may be more strongly retained on packing materials with a high activity of the silanol groups. Therefore, the assumption that a C_{18} packing exhibits more retention than a C_8 packing should be treated with caution.

Most C_{18} and C_8 packings are based on silica with a pore size of around 100 Å (1 Å = 10^{-10} m). This pore size is marginal for peptide separations and too small for the separation of proteins. For this application area, packings with a pore size of 300–500 Å have been designed. Commonly, a gradient is used from 5% or 10% acetonitrile to a high percentage of acetonitrile, with an acidic buffer based on trifluoroacetic acid. Some other mobile phase options are available as well, but are only rarely used.

Reversed-phase packings with an incorporated polar functional group are closely related to the classical C_8 and C_{18} phases. Phases in this group are SymmetryShield™ RP_8 **(14)** and SymmetryShield™ RP_{18} from Waters, USA,[50] Discovery™ RP-AmideC16 and its predecessor Supelcosil™ ABZ + **(15)** from Supelco, USA,[51,52] and the Prism™ column from Keystone Scientific, USA.[53] The common factor among these phases is the fact

(14)

(15)

that a polar functional group is incorporated into the hydrophobic bonded phase.

The incorporation of the polar functional group adds several advantageous properties to these packings. Most important, it suppresses the influence of silanol groups on the retention of basic analytes much more effectively than any other approach used. As a consequence, excellent peak shapes are obtained for basic compounds that exhibit tailing even on the best C_8 or C_{18} packings. Another consequence of the suppression of the influence of silanols is the fact that phases with an incorporated polar functional group exhibit different selectivities from classical C_8 and C_{18} packings, while the overall retentivity is similar to comparable C_8 or C_{18} packings. The third advantage of these phases is the fact that they do not exhibit ''hydrophobic collapse'' as do highly coated classical phases. Hydrophobic collapse is a the name given to a phenomenon observed for the most deactivated reversed-phase packings in highly aqueous mobile phases: suddenly the retentivity of the packing is lost when the flow through the column is stopped for a moment. This occurs because the polar mobile phase is driven out of the pores of a hydrophobic packing owing to surface tension effects,[54] specifically the high contact angle between water and the hydrophobic surface. Since the incorporated polar functional group reduces the contact angle with water and makes the surface more ''wettable'', this phenomenon does not occur.

3.5.2 Evaluation Techniques for Reversed-phase Packings

Reversed-phase packings exhibit a wide range of retention properties that vary with the nature of the analyte. This has created significant interest in a universal characterization of the retention properties of reversed-phase packings. A better understanding of the selectivity of reversed-phase packings would help a user in the selection of a packing.

Several column tests are available that characterize relevant properties of reversed-phase packings. A test developed by Sander and Wise[34,35] is designed to characterize the shape selectivity of a packing, which depends

on the chain spacing of the bonded phase. The selectivity for the shape of the analytes is especially important in the analysis of polynuclear aromatic hydrocarbons. The test mixture, which is available as a National Institute of Standards and Technology (NIST) standard reference material, comprises three aromatic hydrocarbons, BaP, phenanthro[3,4-*c*]phenanthrene (PhPh), and TBN. The elution order of these compounds depends on the coating level, and thus the chain spacing, of a C_{18} bonded phase. For packings with a surface coverage under 3.5 μmol m^{-2}, the elution order is BaP ≤ PhPh < TBN. These packings are considered to be monomeric packings. For polymeric packings with a higher surface coverage, the elution order is PhPh < TBN ≤ BaP. The relative retention between TBN and BaP has been found to vary from 0.6 to 2.2 for a range of commercial packings. This test is useful for the characterization of the density of the surface coating of a packing and can be used to predict the properties of a packing for the separation of aromatic hydrocarbons.

Tests developed by Engelhardt and co-workers[55–57] are primarily designed to test the hydrophobicity and the silanol activity of a reversed-phase packing. The test mixture varied slightly over the history of the test, but consists fundamentally of hydrophobic probes, toluene and ethylbenzene, a mildly acidic probe, phenol, and basic probes such as aniline, *N*,*N*-dimethylaniline or toluidines. The mobile phase is a mixture of 49% methanol and 51% water (w/w). The relative retention between the basic samples and toluene can be used to assess the silanol activity of a packing. High values indicate a high silanol activity. In addition, an increase in tailing for the basic compounds is an indicator of silanol activity. Furthermore, the co-elution of the toluidine isomers is characteristic of a silica with low silanol activity.

Figure 6 Selectivity chart of commercial C_8 and C_{18} packings. The *x*-axis is the natural logarithm of the hydrophobicity of the packing, measured by the retention factor of acenaphthene. The *y*-axis is the natural logarithm of the silanol activity, measured by the relative retention of amitriptyline and acenaphthene at pH 7.00. (The graph is based on data provided by B.A. Alden, Waters Corp.)

A derivative of the Engelhardt test has been developed by Neue and Serowik et al.[2,58,59] The principle of both tests is similar: a mixture of neutral, acidic and basic analytes is used to characterize the overall properties of a packing. The hydrophobicity of a packing is measured via the retention of an aromatic hydrocarbon such as toluene or acenaphthene and the silanol activity is measured using basic analytes such as tricyclic antidepressants or propranolol. These basic analytes exhibit an especially strong interaction with silanols, which makes it possible to run this test in a buffered mobile phase consisting of 65.0% methanol and 35.0% of a 20 mM phosphate buffer at pH 7.00. This test, which originally was designed to test the batch-to-batch reproducibility of the same packing, can also be used to classify different packings. In Figure 6 the results are shown for a multitude of packings. The hydrophobicity is obtained from the retention factor of acenaphthene and the silanol activity is derived from the relative retention of amitriptyline and acenaphthene. Packings with a low hydrophobicity are found on the left side of the graph, packings with a high hydrophobicity on the right side. Packings with a low silanol activity are found on the bottom of the chart, unendcapped packings with a high silanol activity on the top of the chart. Note that both axes are logarithmic! C_8 packings are commonly found on the left side of the chart and C_{18} packings on the right side. Generally, packings based on high-purity silicas with a high coating level cluster together in the lower part of the chart. A line can be drawn between three different packings that are based on the same silica but differ from each other in the C_{18} coating: YMC J'Sphere L80, YMC J'Sphere M80 and YMC J'Sphere H80. This demonstrates the general validity of the chart: at low coating (YMC J'Sphere L80), more silanols are available for interaction, resulting in a high silanophilic activity together with a low hydrophobicity; at high coating (YMC J'Sphere H80), the silanol activity decreases and the hydrophobicity increases. Packings with an incorporated polar functionality are found at the very bottom of the chart, indicating that this design of the bonded phase indeed reduces the influence of silanols on the retention of reversed-phase packings.

Similar tests were developed by Tanaka et al.[60] He proposed use of the retention factor of amylbenzene in 80% methanol as a measure of the number of alkyl chains bonded to the silica and the relative retention between amylbenzene and butylbenzene as a measure of the hydrophobicity of a packing. In analogy to the procedure used by Sander and Wise, the relative retention between triphenylene and *o*-terphenyl is used as a measure of the steric selectivity of a packing. The relative retention between caffeine and phenol measured in 30% methanol/water is used as a measure of the hydrogen bonding capacity of the packing, which depends on the amount of underivatized silanols on the surface of the packing. In addition, the relative retention of benzylamine and phenol is measured at acidic and neutral pH with 30% methanol, as a measure of the ion-exchange sites at both pH values. Since the silanol sites are also the ion-exchange sites, one would expect a reasonable correlation between the relative retention of caffeine/phenol and the relative retention of benzylamine/phenol at neutral pH. However, a buffered mobile phase provides a more controlled environment that is independent of the state of the surface silanols left from the prior history of the packing. The differences between the amount of ion exchange measured at acidic pH and at neutral pH is a measure of the acidity of the surface silanols and is therefore related to the temperature history and the purity of the silica.

The evaluation techniques discussed above have all been used to characterize the retention properties of different packings, but a large scale comparison between the different methods is not yet available. However, smaller scale comparisons reveal a reasonable correlation between some aspects of the different tests. The test developed by Neue and Serowik was originally designed as a batch-to-batch reproducibility test. Therefore, its reliability, reproducibility and simplicity are notable. Tanaka's procedure involves several separate tests, which increases the complexity, but allows the measurement of features that escape the Neue/Serowik test. The main strengths of the Engelhardt test are the selection of test compounds that are readily available to anybody, and a very large body of data.

3.5.3 Batch-to-batch Reproducibility

An important aspect of a packing is the reproducibility of the separations obtained when a new column packed with the same type of packing is used. In general, the reproducibility is impeccable if the same batch of packing is used. However, when different preparations of the same packing are compared with each other, differences in the retention properties can be observed. From some manufacturers, a sufficient part of the specifications of the packing is available to allow a comparison of the reproducibility. A key element is the surface coverage of a packing, which extends beyond the carbon content. For packings for which this information is not available, the user can get an estimate from the specification of the carbon content and the specific surface area, using Equation (4). Examples of the allowable ranges of surface coverage (and therefore reproducibility) are 2.75–3.75 $\mu mol\,m^{-2}$ for Luna™ $C_{18}(2)$ (Phenomenex, USA) or a range of 3.09–3.31 for Symmetry™ C_{18} (Waters Corp., USA). Unfortunately, the information given by

Figure 7 Batch-to-batch reproducibility of three commercial packings. The relative standard deviations (RSDs) for two characteristic parameters are shown: in the foreground, the batch-to-batch reproducibility of the relative retention between two neutral compounds; in the background, the same data are shown for a pair of basic analyte and neutral analyte.

many manufacturers is insufficient to make a judgement on the reproducibility of a packing. However, the characterization tools described in the last section can also be used to test the reproducibility of the preparation of a packing, if proper controls of the mobile-phase composition and column temperature are implemented.[26,27] The best way to assess the reproducibility of a packing is to look at the reproducibility of both a compound pair of very similar properties and a compound pair of widely different properties. An example of the first group is the relative retention of neutral, hydrophobic analytes, such as acenaphthene and toluene. An example of the second group is the relative retention between a basic analyte, such as amitriptyline and a neutral analyte, such as acenaphthene. These data are shown in Figure 7 for three commercial packings. The data were collected over a period of several years.

3.5.4 Other Reversed-phase Packings

Owing to the broad range of available properties, most reversed-phase applications are accomplished with either C_{18} or C_8 columns. Nevertheless, other types of stationary phases have found their niche. The most popular types are phenyl columns **(16)** and cyano columns **(17)**, whose structures are shown below.

(16)

(17)

There are several possibilities for the link between the phenyl group and the silicon attached to the surface. Unfortunately, the information given by manufacturers of phenyl columns is often too vague to establish the way in which a particular phenyl column was designed. For some of the more popular phenyl phases, the structure is known: Nova-Pak Phenyl™ (Waters Corp., USA) is based on a propylphenyl ligand, Zorbax Phenyl™ packings (Hewlett-Packard, USA) use an ethylphenyl ligand, and µBondapak Phenyl™ (Waters Corp., USA) employs an α-methylphenylethyl ligand. Selectivity differences between phenyl phases and classical C_8 and C_{18} phases have been observed, but it is not clear if they can be attributed to the phenyl group or simply to a difference in surface coverage and chain density compared with C_8 and C_{18} packings. Before the introduction of the packings with an incorporated polar functional group, phenyl packings were the tool used by chromatographers to achieve a different selectivity for the separation.

In the early years of chromatography, cyano phases were often employed when different selectivities were sought. However, experience has driven most users away from reversed-phase applications of cyano columns. The hydrolytic stability is about three orders of magnitude lower for CN phases compared with C_{18} phases. In addition, the mechanical stability of CN columns is significantly inferior to other reversed-phase columns. Owing to the multitude of better options, reversed-phase applications of CN columns have been declining.

Very short chains are commercially available as well, but the nomenclature of the designation may not be clear. A phase designated C_3 by one manufacturer may be identical to a C_1 phase of another manufacturer and the bonded phase is based on a trimethylsilane. These very short chains have a better hydrolytic and mechanical stability than CN phases and can be used with advantage. Short chains, commonly C_4 **(18)**, are used for the reversed-phase separation of proteins. In this case, the pore size of the silica is larger, typically 300 Å or 500 Å.

(18)

3.5.5 Bonded Phases for Other Types of Chromatography

While the predominant use of bonded phases is in the world of reversed-phase chromatography, other application areas should not be overlooked. A few phases, commonly abbreviated as cyano **(19)**, amino **(20)**, diol **(21)**, and nitro **(22)** are used in normal phase

chromatography. The diol and amino phases are mostly utilized in highly specific application areas.

Most polar bonded phases are based on trifunctional silanes. On one hand, this adds to the hydrolytic stability, on the other hand the influence of a large population of silanols on the separation should be considered.

Compared with silica columns, bonded phases are less sensitive to the water content of the mobile phase, which improves the reproducibility of a normal-phase separation. In addition, significantly different selectivities can be achieved. However, manipulation of the selectivity of a separation is rarely a problem in normal-phase chromatography, since a wide range of mobile phase options is available.[2]

Cyano packings are the least polar of the packings used in normal-phase chromatography. While there is little concern about the hydrolytic stability of CN phases in normal-phase chromatography, care should still be exercised with respect to the mechanical stability, especially when solvents of intermediate polarity are used to wash the columns in a clean-up procedure.

Nitro phases, or better nitrophenyl phases, have been used in the normal-phase separation of aromatic hydrocarbons. The separation mechanism is influenced by the formation of $\pi-\pi$ bonds between the analytes and the bonded phase. The consequence is a group separation of the aromatic hydrocarbons based on the number of rings. Nitro phases with more than one nitro group per ring have also been designed. This increases the strength of the $\pi-\pi$ interaction. Occasionally, a reversed-phase application of nitro phase is found as well.

While applications of diol columns in normal phase chromatography are comparatively rare, this stationary phase nevertheless presents an interesting polar alternative to silica, since it is less sensitive than silica to the water content of the mobile phase. However, the primary application area of diol columns is in aqueous size-exclusion chromatography, especially of proteins. High coating levels largely suppress the interaction of proteins with the underlying silica, provided a mobile phase with a salt concentration between 0.1 and 0.5 mol L^{-1} is used. At lower salt concentrations, the influence of residual silanols on retention becomes apparent, at higher salt concentration, hydrophobic interactions distort the separation. Figure 8 shows a gel filtration separation of protein standards using a diol column. Another, less commonly used application area of diol columns is hydrophilic interaction chromatography, using acetonitrile–water mixtures with a high acetonitrile content for the separation of very polar compounds.

Figure 8 Size-exclusion separation of protein standards on a diol column. Column: Waters Protein-Pak 300SW, 7.8 mm × 300 mm. Mobile phase: 0.1 M K_2HPO_4, pH 7.0; flow rate: 1.0 mL min^{-1}; detection: 280 nm (chromatogram courtesy of Waters Corporation).

In normal-phase chromatography, amino columns are another interesting alternative to underivatized silica. A special application is related to the main application of nitrophenyl packings: the class separation of aromatic hydrocarbons. The separation patterns are similar for both columns: in both cases, the analytes are separated into groups of common ring size. However, the primary application area for amino columns is in hydrophilic interaction chromatography for the separation of carbohydrates (Figure 9). The separation mechanism[61] for the sugar separations is a partitioning mechanism between a mobile phase with a low water content and the stationary phase with an enriched water content. The main advantage of the amino column over other polar packings (such as diol) is the fact that amino columns do not separate the sugar anomers, while other polar phases do. The reason for this is the fact that the local basic environment promotes the interconversion of the anomers during the chromatographic run. Therefore, all sugars elute as single, albeit somewhat broad peaks. It should be noted though that silica-based amino phases

Figure 9 Separation of sugars using an aminopropyl bonded phase. Column: Waters High-Performance Carbohydrate Column. Mobile phase: acetonitrile/water 75/25 v/v (chromatogram courtesy of Dorothy Phillips, Waters Corporation).

are not completely stable in an aqueous environment: the high concentration of amino groups in the pores of the packing creates a high pH value, which leads to a partial dissolution of the silica and the bonded phase. This occurs until a sufficient number of acidic silanol groups is available to reduce the local pH. Therefore, amino columns for the separation of sugars are commonly pretreated to reach a stable arrangement.

Another group of stationary phases based on silica are the ion exchangers **(23)** and **(24)**. Both strong cation and strong anion exchangers are commercially available. The anion exchanger can be prepared by direct synthesis or by a secondary reaction of a dimethylaminopropyl silane bonded phase with a methylating reagent. Two types of cation exchangers are possible: one is based on a purely aliphatic chain, the other is based on an aromatic sulfonic acid. Similarly, quarternary amines based on an aromatic core group in the bonded phase are possible as well.

(23)

(24)

The application literature is not as extensive as the application literature using classical ion exchangers based on an organic backbone. This is mostly due to the limitations in the pH range imposed by the silica backbone. In addition, ion-pair chromatography[62] based on well-defined reversed-phase packings has become a more versatile substitute for ion-exchange separations of small molecules.

However, ion-exchange chromatography remains one of the primary tools in the separation of biomacromolecules. The special phases for this application fall into the category of coated phases and are discussed in the next section.

4 COATED PHASES

In this section, the properties of silica-based coated phases are discussed. The coating consists of a physically adsorbed or chemically bonded and/or crosslinked polymer layer that modifies the adsorption properties of the substrate by superimposing its own properties. Properly executed, it should be possible to combine the advantageous properties of the coating with the mechanical strength of the silica. Note that many of the stationary phases discussed in this section can be prepared on inorganic substrates other than silica. The advantage of other substrates lies in the improved pH stability compared with silica: silica dissolves with an appreciable rate at pH values exceeding 9 at room temperature, therefore substrates like alumina, titania, or zirconia have marked advantages. Nevertheless, most work has been done using silica as the base material.

In general, very few phases with a polymeric surface layer have been commercially successful. Prevailing applications include packings designed for the chromatography of macromolecules like proteins[63–65] and packings for special applications, e.g. ion chromatography.[66–68] The reason for this limited success is the inferior mass-transfer properties of coated phases for small molecules, which is due to the fact that the polymeric layer can be at least partially penetrated by small molecules and that diffusion in the polymeric layer is slow. This feature is shared with fully organic packings. The problem either becomes irrelevant, if no packing with equivalent selectivity and good mass transfer is available, or disappears, if the molecular weight of the analytes is sufficiently large, as is the case for proteins.

Many different polymers have been immobilized on silica. Petro and Berek[68] list some 80 different types of polymer–silica combination. The polymeric layer may be bonded to the surface, or cross-linking may keep it in place without attachment to the surface. If the polymer is not generated in situ, an important consideration in the preparation is the access of the polymer to the pores of the packing. Therefore, four different preparation procedures for polymer-coated packings can be differentiated:[70]

1. polymerization or polycondensation of monomers without bonding to the surface
2. polymerization or polycondensation of monomers with bonding to the surface
3. immobilization of prepolymers without attachment to the surface

4. immobilization of prepolymers with attachment to the surface.

In the following, these different approaches are described briefly.

4.1 Preparation Techniques for Coated Phases

4.1.1 Polymerization or Polycondensation of Monomers Without Bonding to the Surface

In this approach, the monomers are first coated into the pores or onto the surface of the silica. Then, the polymerization is initiated. Since it is not difficult to generate a uniform coating of the surface with the monomer(s), such a process should then result in a uniform polymeric coating of the packing as well. However, results obtained with this technique[71,72] were rather disappointing, when small analytes were investigated: for thin layers, the silica matrix was poorly shielded by the polymeric layer and influenced the retention of basic analytes, while thick layers resulted in an inferior mass transfer and broad peaks for small analytes. The results are shown in Table 2. The influence of silanols on the retention of basic analytes can be measured by the relative retention between propranolol and acenaphthene; as the coating level increases, the relative retention becomes smaller, i.e. the relative influence of silanols on the retention drops. However, the mass-transfer term, measured with toluene as sample, increases as the coating level increases. On a C_{18} column based on the same silica, the mass-transfer term for toluene was only 3 ms. This clearly exemplifies the general problem of polymeric coatings on silica or other inorganics: polymeric coatings result in inferior mass transfer and thus inferior plate counts for small molecules.

4.1.2 Polymerization or Polycondensation of Monomers with Bonding to the Surface

When at least one of the monomers used in the polymerization is attached to the surface, better adhesion of the resulting polymer to the surface is expected and a more conformal coating should be achievable. Packings prepared using this approach have been reported by Engelhardt and co-workers[72,73] and are commercially available under the trade name Polyencap™ (Bischoff GmbH, Germany). The packings are prepared by first bonding vinylsilane to the silica surface, then coating the resulting surface with an acrylate monomer, which is then polymerized along the surface. Generally, good mass-transfer properties have been reported for these packings, but owing to the low coreactivity of vinylsilane with the monomers, a clear picture of the nature of the resulting surface is not available. In this procedure, only 50–80% of the monomer was incorporated in the packing and chemically anchored to the surface, demonstrating the low coreactivity of the vinylsilane with the monomers.

Table 2 Properties of 10 μm Spherisorb® silica with divinylbenzene polymer layers

Nominal layer thickness	Coating %	α-Propranolol/ acenaphthene	Mass transfer term (ms)
1/4	2.56	2.3	17.8
1/2	5.2	2.2	15.1
1	10.1	1.9	21.8
1.5	14.6	1.6	18.4
2	18.1	1.3	26.9

The method used for the preparation of a range of commercial silica derivatives used for the separation of biopolymers (PolyLC, USA) is related to this approach. In this procedure,[63–65] silica of the correct pore size is first derivatized with aminopropyltriethoxysilane in toluene. The resulting amino-bonded phase is then treated with poly(succinimide) at room temperature in tetrahydrofuran (THF). This phase can then be used to prepare a range of derivatives, e.g. a poly(aspartic acid) derivative by reaction with β-alanine as a weak cation exchanger, a poly(2-aminoethyl aspartamide) derivative from ethylenediamine as a weak anion exchanger, poly(alkyl aspartamide) derivatives for hydrophobic interaction chromatography,[64] a poly(2-sulfoethyl aspartamide) derived from taurine as a strong cation exchanger,[65] and a poly(2-hydroxyethyl aspartamide) derivative for hydrophilic interaction chromatography.[74] These packings have been used extensively in the separation of proteins and peptides. While data for the mass-transfer behavior of these packings for small molecules are not available, the quality of the gradient separations of proteins and peptides is impressive.

Another successful group of packings in this category is the group of ''tentacle'' ion exchangers (Merck, Germany) which are also employed in the chromatography of biopolymers.[75] The difference between classical ion exchangers and the tentacle type is the location of the ion-exchange groups on the packing. For classical ion exchangers, the ion-exchange groups are located on the internal surface of the packing. For tentacle ion exchangers, they are located on linear polymer chains grafted to the support surface. The free access to the ion-exchange groups improves the interaction with biopolymers, while avoiding distortions of the three-dimensional conformation of the analytes. Consequently, significantly different selectivities have been observed compared with classical ion exchangers and improved chromatographic performance has been reported. However, as for any other packing for the

chromatography of biopolymers, a quantitative measurement of the mass-transfer properties[2] of the tentacle packings is not available, which makes an objective judgement of the quality of the packing difficult.

4.1.3 Immobilization of Prepolymers Without Attachment to the Surface

In the third approach, a low-molecular-weight polymer is coated onto the surface and then immobilized through chain extension or crosslinking. Examples of this approach have been pursued by Schomburg et al.[76] Of course, whenever procedures are used that can generate a nonbonded coating on silica, other inorganics can be substituted with advantage. Poly(butadiene)-coated alumina exhibits an improved pH stability relative to silica-based sorbents. However, while no concrete data on column efficiency or mass transfer are available in the literature, a decrease in column performance relative to classical phases has often been observed. However, this is not an impedance for specific applications. Schomburg's group also coated silica with a copolymer of butadiene and maleic acid to create a cation exchanger.[77] The most popular application of this packing is the simultaneous separation of alkali and alkaline earth ions in a single isocratic chromatographic run (Figure 10), which is not achievable with any other packing.

The coating of silica with polybutadiene[78] or with poly(methyloctylsiloxane)[79] has been investigated in detail. In the latter study, it was demonstrated that the surface area decreases linearly with the specific loading of polymer onto the silica and that this behavior is inconsistent with a uniform film coating the surface of the packing. In the former study, a broad arsenal of tools ranging from nitrogen sorption to solid-state NMR was employed to demonstrate the same feature: ''polybutadiene coatings on silica do not result in a homogeneous polymer film but in an inhomogeneous loading...'', and ''an increasing polymer loading leads to increasingly filled pores instead of a thicker polymer film''.[78] Until now, the problem of generating a uniform polymeric film on the surface of a sorbent without bonding to the surface remains unsolved.

Figure 10 Separation of alkali and alkaline earth ions on poly(butadiene-maleic acid) coated silica. Column: IC-Pak C M/D, 3.9 mm × 150 mm, Waters Corporation. Eluent: 0.1 mM ethylenediaminetetraacetic acid, 3.0 mM HNO_3; flow rate: 1 mL min^{-1}; sample: 1. lithium, 2. sodium, 3. ammonium, 4. potassium, 5. magnesium, 6. calcium; detection mode: conductivity (chromatogram courtesy of Waters Corporation).

For the separation of proteins, polyethyleneimine was coated onto silica and crosslinked.[80] This durable anion exchanger has been successfully employed in the separation of many biopolymers. It could be argued that the polyethyleneimine is attached to the surface via an ion-exchange interaction and that this packing belongs to the category discussed in the next paragraph.

Both techniques have been used to coat small nonporous silica spheres as well. The principle behind this approach is to take advantage of the more rapid mass transfer of nonporous particles for the fast separation of macromolecules. For example, polybutadiene was coated onto nonporous silica spheres of 1.7 μm diameter.[81] The small particle diameter together with the fact that the packing was nonporous allowed for rapid gradient separations of peptides. In an earlier publication,[82] the coating of nonporous silica spheres with polyethyleneimine was investigated. Very rapid separations of proteins and nucleotides were obtained.

4.1.4 Immobilization of Prepolymers with Attachment to the Surface

An example of the immobilization of a prepolymer with attachment to the surface of silica has been published by Petro et al.[83] The purpose for the design of such a phase was the size-exclusion chromatography of proteins. The silica is first reacted with γ-glycidoxypropyltriethoxysilane in dry toluene. The resulting product is then further derivatized with aqueous solutions of dextran or ethylenediamine derivatives of dextran at various pH values in water. Unfortunately, a significant amount of interaction with silanols remained on the packing, requiring still higher salt concentrations (0.25 M) to elute proteins in size-exclusion mode.

In another example,[84] polyvinylpyrrolidone was coated onto large pore silicas. First, a copolymer of vinylmethyldiethoxysilane and vinylpyrrolidone was created. Then this polymer was attached to the silicas via the active silane groups. Finally, the material was endcapped using a standard process. Both size-exclusion chromatography and hydrophobic interaction chromatography of

proteins were possible with this packing. However, the packing loses attractiveness owing to the necessity of following through with the hydrolytically weak endcapping step.

4.2 Properties of Coated Phases

Most investigations of silica-based coated phases have been focused on the preparation of materials for the separation of biomolecules. This is largely due to the fact that most phases in this category suffer from restricted mass transfer for small molecules and therefore inferior column performance. The most promising category for small molecules appears to be the second category, where the preparation involves a polymeric surface coating from monomers with a known attachment to the surface.

For proteins and other large molecules, the same principle has also yielded the most promising results. The long-standing success of the phases described by Alpert[63–65,74] as well as the newer success of the tentacle phases support this approach. Nevertheless, one needs to differentiate between reality and marketing claims. In a fundamental study, Ratnayake and Regnier[85] studied the protein binding capacity of ion exchangers prepared by the second principle. They concluded that the mechanism of adsorption is similar between tentacle-type ion exchangers and surface-bound ion exchangers. Among other things, the *Z*-number, which is a characteristic value for the number of the interaction sites between ion exchanger and analyte, was similar for both types of sorbents. The increased capacity of tentacle-type ion exchangers compared with surface-bound ion exchangers is therefore simply due to an increased number of available exchange sites owing to the larger surface area of the tentacle-type packings.

The other issue for the separation of macromolecules is the plate count achievable with different packings. Unfortunately, the techniques that allow a determination of the plate height under gradient conditions[3] have not yet been applied to these packings and therefore an objective comparison is not yet possible. It might be expected that the situation is similar to the situation for small molecules: nonporous packings exhibit a higher plate-count performance, but a lower capacity than porous packings. However, the differences are expected to be much smaller owing to the necessity of taking into account larger pore sizes for macromolecules compared with smaller molecules. With respect to the performance of coated phases compared with classical bonded phases, a lesser sensitivity of the HETP for macromolecules on the details of the surface coating can be expected. The success of the Alpert phases and the tentacle phases supports this expectation.

5 SUMMARY

The classical derivatization of silica has become the main tool for the preparation of stationary phases for classical HPLC, i.e. the separation of small molecules. The influence of the properties of the silica and the stationary phase are well understood. Nevertheless, progress continues to be made. The success in the 1990s of high-purity silica as the carrier of bonded phases is the dominant example. On a smaller scale, bonded phases for reversed-phase chromatography with incorporated polar functionality are now more widely used owing to their improved peak shape compared with classical packings. The newest development for the analysis of small molecules are the continuous rod structures, whose success will be determined in the future.

Until now, silica-based stationary phases have played a more limited role in the HPLC separations of biopolymers. Some innovative approaches have been applied and progress has been made, but silica-based phases are only one of many tools used in the separation of biomolecules. The more promising approaches use a polymeric coating of the silica to combine the benefits of the strength of silica with the biocompatibility of the polymeric coating.

In addition to the information presented in this article, the literature contains supplemental or related specific information. Dorsey et al.[86] review fundamental developments in the LC literature from October 1995 to October 1997. Leonard[87] gives a general review of new packing materials for protein chromatography, including polymer-based and silica-based packings. Interested readers are referred to these review articles.

Supercritical fluid chromatography (SFC) employs fluids that are raised above their critical pressure (P_c) and critical temperature (T_c) as mobile phases. Carbon dioxide, CO_2, is the supercritical fluid most commonly used as a mobile phase for SFC. It is capable of solvating mostly nonpolar analytes. Cosolvents, such as methanol and acetonitrile, are added to increase the polarity of the analytes that can be analyzed by SFC. SFC is most commonly practiced using a normal-phase retention mechanism. In other words, the stationary phase is typically more polar than the mobile phase and the retention order is in increasing order of polarity. The advantages of SFC over liquid chromatography (LC) include higher efficiency separations and faster speed of analysis. The advantage that SFC has over gas chromatography (GC) is that SFC can efficiently separate thermally labile compounds. The disadvantage of SFC is that the polarity of the mobile phase is limited. Highly polar solutes are not soluble in supercritical fluids, even when modifiers are added. SFC is commonly used to separate petroleum distillates and by-products, moderately polar pesticides and herbicides, and more recently for the separation of chiral compounds, such as pharmaceutical drugs.

1 INTRODUCTION

SFC employs fluids at temperatures and pressures above their critical temperatures (T_c) and critical pressures (P_c). When used as chromatographic mobile phases, supercritical fluids are able to solvate moderately polar analytes that are difficult to volatize in GC, but are still compatible with GC detectors. Whenever analytes could be separated by either LC or by SFC, the latter provides higher efficiency, shorter analysis time, lower pressure drop across the column and wider choices of detectors. Of the numerous supercritical fluids studied, carbon dioxide has found the widest application in SFC due to a number of advantages, including mild critical parameters, inertness, environmental friendliness, low cost and easy access to high purity. With solvating power equivalent to that of pentane or hexane under supercritical conditions, pure carbon dioxide cannot solvate and elute high polarity analytes very easily. Recent developments in the applications of polar modifiers to the carbon dioxide mobile phase in packed column supercritical fluid chromatography (pSFC) have established the place of SFC in modern chromatographic sciences. Other high fluidity mobile phases are also under study.[1–3] These include subcritical, near-critical, enhanced-fluidity liquids and solvating gases.

In this chapter, the fundamental merits of using supercritical fluids and other high fluidity mobile phases in chromatography, the relationship of SFC to GC and high-performance liquid chromatography (HPLC), instrumentation of SFC and common mobile and stationary phases are discussed.

2 THEORY AND PRINCIPLES OF SUPERCRITICAL FLUID CHROMATOGRAPHY

2.1 Properties of Supercritical Fluids

A supercritical fluid corresponds to a condition where the compound is compressed above its critical pressure (P_c) and heated above its critical temperature (T_c) (Figure 1). Supercritical fluids have properties that are similar to those of both gases and liquids. The density of a supercritical fluid is close to that of a liquid, while its viscosity approaches that of a gas, and diffusion coefficients of supercritical fluids are typically intermediate between those of gases and liquids (Table 1). The phase change between gas and liquid is accompanied by abrupt physical property changes. However, the transition to and from the supercritical state is continuous and no abrupt changes in physical properties occur when passing through the critical point.[4] Figure 2 shows the approximate regions occupied by mobile phases used in GC, SFC and LC on a diffusion coefficient, D_m, vs density, ρ, plot.[5] Also, Figure 2 clearly shows the large difference in diffusion coefficients between gases and liquids.

Because supercritical fluids are highly compressible, the properties of supercritical fluids vary with pressure. For example, the density of supercritical CO_2 at approximately 40 °C can be varied from 0.25 to 0.8 g cm^{-3} by changing the pressure from 75 to 300 bar.[6] Accordingly, the solvent strength of a supercritical fluid can be varied by changing the pressure, which also means that analyte solubility is controlled by pressure variation. Similarly,

Figure 1 Phase diagram for a pure substance. The regions for the three phase states are labeled. When temperature and pressure are above the critical point of the substance, a supercritical state is obtained.

Table 1 Typical physical properties of gases, supercritical fluids and liquids

	Density (g mL^{-1})	Viscosity (cP)	Self-diffusion coefficients (cm^2 s^{-1})
Gas (30 °C, 1 atm)	$0.6–2 \times 10^{-3}$	$1–3 \times 10^{-2}$	0.1–0.4
Supercritical fluid	0.2–0.9	$1–9 \times 10^{-2}$	$0.2–0.7 \times 10^{-3}$
Liquid (30 °C, 1 atm)	0.6–1.6	0.2–3	$0.2–2 \times 10^{-5}$

Figure 2 Schematic illustration of the relationship between the diffusion coefficient (D_m) and density (ρ) of mobile phases in GC, SFC and LC. The relatively defined regions occupied by the mobile phases of GC and LC are bridged by the elongated region for SFC. (Reproduced from Schoenmakers and Uunk[5] by permission of Marcel Dekker, Inc.)

mass transport properties, such as viscosity and diffusion rates, vary with pressure. The precise control of solvent properties by fine tuning the pressure of supercritical solvents is unsurpassed by any other phase.

Carbon dioxide, CO_2, is the most commonly used supercritical fluid. Its low critical temperature and pressure (31.3 °C and 72.8 atm) allow most separations to be undertaken near room temperature. CO_2 also has low toxicity and is environmentally benign. CO_2 is also highly compatible with a large range of detectors. However, the solvent strength of CO_2 is low. Even under high pressures, polar analytes will not dissolve in supercritical CO_2.

The solvent strengths of supercritical fluids were experimentally measured by monitoring the shift of the ultraviolet/visible (UV/VIS) absorbance maxima for a number of solvatochromic dyes.[7–10] The solvent strength of CO_2 was shown to be close to that of pentane

or hexane.[6] Despite the low polarity of supercritical CO_2, it remains the dominant mobile phase for SFC in applications to date due to the merits referred in the previous section. Furthermore, polarity enhancement of CO_2-based mobile phases is accomplished by the addition of polar modifiers and/or additives.

2.2 Why Supercritical Fluid Chromatography?

The major chromatographic advantages of using supercritical fluids are lower viscosity and higher diffusivities and concomitant higher efficiency, increased speed of analysis and lower pressure drop, as compared to LC. The connection between fast mass transport properties and improved chromatographic performance is delineated in the following sections.

2.2.1 Band Dispersion as a Function of Mobile Phase Velocity

The van Deemter equation will be used to correlate chromatographic efficiency with the mobile phase velocity. An uncoupled van Deemter equation[11] for packed columns in LC is given by Equation (1):

$$H = A + \frac{B}{u} + Cu \tag{1}$$

where H is the plate height (or band dispersion), u is the linear velocity of the mobile phase, and A, B and C are velocity-independent parameters that are determined by the properties of the mobile and stationary phases. The A term is the contribution from multiple flow paths of a packed column, the B term is the contribution to band dispersion from longitudinal (along the flow axis) diffusion and the C term represents the combined obstruction of mass transfer in the mobile phase and the stationary phase or C_m and C_{sm}. The B and C terms can be further expressed by Equations (2) and (3):

$$B = \gamma D_m \tag{2}$$

$$C = \frac{f(k')}{D_m} \tag{3}$$

where γ is the obstruction factor, k' is the retention factor and D_m is the average diffusion coefficient of the solute in the column. For incompressible mobile phases, D_m is independent of pressure, while for compressible mobile phases, such as in GC and SFC, D_m is influenced by flow rate when column pressure is a function of flow rate. More complicated expressions have been used to approximate the relationship between the average column pressure and the flow rate for compressible mobile phases.[12] Nevertheless the results from the more complicated model were comparable to the conclusions shown below. For the sake of simplicity, the independence of D_m on the column flow rate is assumed.

By taking the first derivative of Equation (1) with respect to u and setting the derivative to zero, the optimal mobile phase velocity, u_{opt}, for the minimum plate height, H_{min}, is obtained, as shown in Equations (4) and (5):

$$u_{opt} = D_m \sqrt{\frac{\gamma}{f(k')}} \tag{4}$$

and

$$H_{min} = A + \sqrt{2\gamma \times f(k')} \tag{5}$$

Equation (4) shows that u_{opt} is proportional to D_m; thus, the mobile phase with higher solute diffusivity gives higher u_{opt}. Since the diffusion coefficient of a solute in a supercritical fluid is larger than that in liquids, the u_{opt} using supercritical mobile phases is higher than using a liquid solvent. At high velocities the plate height is dominated by the C term, and is inversely proportional to D_m. Higher D_m values result in a small C term, which means smaller band dispersion and higher efficiency in the high velocity range. Equation (5) indicates that H_{min} (or maximum efficiency) is independent of D_m or the mobile phase properties. In other words, the maximum efficiency using a particular column is irrelevant to the type of chromatography, i.e. in principle GC, SFC and LC generate the same efficiency at their individual optimal flow rates. However, practically, the optimal linear velocity, u_{opt}, for LC using a typical column is small. Thus, the routine practice of HPLC is at much higher linear velocity than its optimum value, which results in lowered efficiency. At a high mobile phase velocity, the efficiency decreases in the order of GC, SFC and LC. In summary, for samples previously only amenable to HPLC, SFC provides higher efficiency and shorter analysis time, while for samples just beyond the scope of GC, SFC analysis is not compromised severely on efficiency and analysis time.

2.2.2 Effect of Viscosity on Chromatographic Performance

Equation (6) shows the relationship between the pressure drop and the mobile phase viscosity as described by Darcy's law:[13]

$$\Delta P = \frac{\phi \eta u L}{d_p^2} \tag{6}$$

where ϕ is a dimensionless flow resistance parameter, η is the viscosity of the mobile phase, u is the average linear velocity, and L and d_p are the column length and the particle diameter. Darcy's law indicates that a lower pressure drop across the column can be obtained by decreasing

the viscosity of the mobile phase. Therefore, for the same column and flow rate, SFC has a lower pressure drop than LC. The lower pressure drop across a column in SFC allows longer columns or more columns to be coupled together to obtain higher efficiency and better separation.

2.3 Closely Related Chromatographic Techniques and Unified Chromatography

The properties of a fluid,[4,14,15] i.e. density, viscosity, diffusion coefficient and solvating power, change continuously near the critical point. Therefore, chromatographic systems using other portions of the phase diagram that are near the critical point may have merit as well. Subcritical fluid chromatography (chromatography done under liquid state conditions that are near the critical point) often has similar objectives and uses the same instrumentation as SFC. Sometimes, subcritical fluids are preferred to supercritical fluids when the critical temperatures of the mobile phases are too high, or the analytes are thermally labile. For example, because chiral separations are often enthalpy controlled, the selectivity of the separation is improved by decreasing the temperature of the separation (i.e. using subcritical conditions).

Other approaches have also been taken to generate mobile phases with low viscosities and high diffusivities. These include high-temperature liquid chromatography (HTLC) and enhanced-fluidity liquid chromatography (EFLC). In high temperature HPLC the column temperature is raised to lower the mobile phase viscosity. For example, at 60 °C the viscosity of water is about half of that at 20 °C.[16] HTLC using heated water (up to 210 °C and 20 bar)[17,18] and acetonitrile (up to 150 °C)[19] has been reported. The lower viscosity at high temperatures is accompanied by higher vapor pressure and the column outlet pressure was increased above atmospheric pressure to prevent the mobile phase from boiling. Enhanced-fluidity HPLC involves the addition of a low-viscosity liquid, such as liquid CO_2 or liquid fluoroform, to organic solvents. This greatly lowers the viscosity of the solvent while maintaining a solvent strength similar to that of the pure organic solvent.[20,21]

While SFC fits between GC and LC, HTLC and EFLC are techniques that provide a continuum between SFC and LC, and solvating gas chromatography (SGC)[22] is an effort to bridge the gap between GC and SFC. In SGC, where capillary SFC instrumentation is commonly used, high pressures are exerted at the column inlet to maintain a supercritical, subcritical or liquid state of the mobile phase, but low pressures (slightly higher than atmospheric) at the column outlet result in phase transitions down the length of the column. Examples of SGC include the use of carbon dioxide[23] and ammonia as mobile phases.[23]

In all these studies, a common and key point is to maintain the column outlet pressure at a pressure greater than atmospheric pressure. Once the outlet pressure is controlled, gases can be compressed to supercritical fluid conditions or liquid state conditions. In fact, the mobile phase can essentially span between liquid and gas phases depending on the application without the necessity to distinguish the exact state in practice. This prompted the concept of ''unified chromatography''.[24,25]

2.4 Capillary Supercritical Fluid Chromatography Versus Packed Column Supercritical Fluid Chromatography

Capillary supercritical fluid chromatography (cSFC) experienced rapid development in the 1980s, while pSFC did not rival and prevail over cSFC until the early 1990s. Although packed capillary columns are also used,[26] cSFC will be used in this text to refer to open tubular capillary column SFC.

cSFC and pSFC differ in instrumentation and application. The column pressure of cSFC is usually maintained through the upstream pump and the after-column fixed restrictor. Higher flow rates are associated with higher column pressures. Owing to the low ratio between the stationary phase volume to column void volume, cSFC has a lower pressure drop per unit column length, which allows long column lengths to be used to achieve high efficiency. cSFC has high peak capacity and is well suited to analyze complex mixtures.[27–29] In cSFC a single pump is used to deliver a neat mobile phase and pressure programming is common. Direct coupling of GC detectors, such as flame ionization detectors (FIDs), is advantageous for high sensitivity measurements. However, insufficient solvating power of the mobile phase (CO_2 normally) even at high pressures precludes it from analyzing moderate or highly polar compounds.

pSFC is primarily used for analysis of polar analytes that are beyond the scope of cSFC through the use of polar modifiers. It has a larger ratio of the stationary phase volume to column void volume, leading to higher retention and necessitating the use of stronger eluent, such as polar modifiers. Compared with cSFC, pSFC has a higher flow rate and consequently a high pressure drop. The pressure gradient along the column results in gradients of mobile phase density, diffusion coefficient of the solute and flow rate along the column. Although pressure drops can be greater than 100 atm, no serious compromise on column efficiency is observed.[30–32] pSFC gives shorter analysis time and higher efficiency per unit time. The large mass flow permits the usage of a double pump system for preparing binary or ternary mobile phases. It also makes independent control of flow rate and

pressure possible, which is critical in decoupling the two for method development and optimization. The column pressure is controlled by a (electronically controlled) pressure regulator placed after the column. Polar modifier and/or additive, supplied from the second pump, are normally used to enhance the eluting power and solubility of analytes. pSFC uses LC columns, which provides a wide stationary phase selection. Inherently, pSFC exhibits higher sensitivity, reproducibility and sample loadability. However, pSFC cannot use some GC detectors, such as FIDs, due to the presence of the modifier. Recent advances in technology have made modern packed column supercritical fluid chromatographs commercially available, which has greatly promoted the development and popularity of pSFC.

3 INSTRUMENTATION

The main components of the SFC chromatograph include pump, injector, oven, column, pressure control device and detector. The instrumentation used for cSFC and pSFC is not the same. Schematic block diagrams for chromatographs used in pSFC and cSFC are shown in Figure 3.

3.1 Pump and Mixer

The chromatograph for cSFC usually contains a single syringe pump for delivering neat or premixed mobile phase, while that for pSFC often contains a high pressure reciprocating pump and an additional microflow high pressure pump for delivering the modifier and additive. The syringe pump in cSFC typically delivers mobile phase fluid at a rate of 1 to 80 $\mu L\,min^{-1}$, whereas, the reciprocating pump in pSFC works in a range of 0.5 to 10 $mL\,min^{-1}$ and the microflow pump delivers modifiers in the range of 1–20% of the fluid.[33–36] The mobile phase, e.g. CO_2, is normally from pressurized cylinders. For precise delivery of the fluid, compressibility compensation has to be included in the pumping process. For pSFC, owing to the large flow rate, a reciprocating pump is required for uninterrupted delivery of the mobile phase. Precise control of temperature at the pump head is essential for compressibility compensation.[37] Because the compressing process is exothermic, the pump head is usually well chilled using a circulating bath or thermoelectric (Peltier) cooler.

For pSFC, the pressurized fluid and modifier are dynamically mixed at the high pressure mixer. A pulse damper is usually placed in line to smooth the fluid pulsation produced by reciprocating pumps.

Figure 3 Schematic diagrams showing the instrumental set-up for (a) pSFC and (b) cSFC. In pSFC, two pumps and an online mixer are normally used to deliver a mixture of mobile phases. The column outlet pressure is maintained by the back pressure regulator. To use GC detectors, flow splitting before the back pressure regulator is necessary. In cSFC, a single pump is normally used to deliver pure or premixed mobile phase. The column pressure is controlled at the inlet by the pump, resulting in the coupling of column pressure and flow rate.

3.2 Sample Injection

The amount of sample that can be introduced depends on the type of SFC. In cSFC, the injection volume is about 0.5 nL. To obtain reproducible injections for such a small volume, an injection valve with a split mechanism is necessary. Currently, two designs are commonly used, the split/splitless[33,38] and the timed-split.[36,39] Both allow injection of only a fraction of the sample loaded in the internal loop.

In pSFC a standard LC rotary injector with loop size of 5 to 20 μL can be used. When a large loop size is used, special precautions should be taken when switching the valve from injection position to loading position to minimize band dispersion because the expansion of the high-pressure fluid is vigorous. Since SFC is usually normal-phase chromatography (see discussion later), an injection solvent of weaker polarity than the mobile phase is preferred in order to minimize interference of the injection solvent with the analyte retention. When injection solvents are used that are too strong, analytes tend to flow down the column with the solvent plug for a significant fraction of the column length instead of interacting with the stationary phase. This leads to peak widening and poor selectivity. Thus, when polar solvents (e.g. water or methanol) cannot be avoided, the injection volume should be minimized. When large volumes of diluted solute are to be used, preconcentration or adsorption of the solute onto a precolumn or guard column mounted at the loop position is useful.

3.3 Column and Oven

The column temperature of cSFC is maintained using GC-type ovens. pSFC uses LC-type ovens. An upper temperature limit of 200 °C is normally sufficient. In fact, a significant proportion of the published pSFC experiments are run at subcritical conditions. Furthermore, the capability of the pSFC oven to lower temperature to subzero ranges is beneficial for enhancing selectivity of the separation, particularly for chiral separations.[40,41]

The columns for cSFC are typically made of fused silica with diameter of 0.025 to 0.1 mm and length of 1 to 35 m. The stationary phases are discussed in detail in a later section. The columns for pSFC (including microbore columns) are the same as those used in LC with dimensions of 0.5 to 4.6 mm inner diameter, 3 to 25 cm long and are normally made of stainless steel. Typical pSFC columns are packed with totally porous silica particles 3 to 10 μm in size.

3.4 Pressure Control

The mobile phase flow rate in cSFC is maintained typically by placing a small diameter open tube at the end of the column.[42] The pressure of the cSFC system is controlled by the outlet pressure of the pump. A pressure gradient, frequently used in cSFC, is generated by a programmed flow rate gradient. However, decreased column efficiency will result if the flow rates become too high. Independent pressure control and flow rate control in cSFC by using a pressure regulator with very small dead volume to accommodate the mass flow is still too technically challenging. However, precise independent pressure control is possible and has been implemented in pSFC by placing a pressure regulator after the column. An electromagnetically controlled needle or piston inside the regulator controls the closing and opening of an orifice in conjunction with the flow rate to maintain a specified pressure.

3.5 Detection

Generally speaking, SFC is superior to HPLC in the range of compatible detection methods, because most detectors used in GC can also be used in SFC, particularly for CO_2-based mobile phases. The applicability of a specific detector, though, depends on the nature of the analyte, flow rate and composition of the mobile phase.

The compatibility of SFC with the FID is one of its strengths. As a universal detection method with high sensitivity and wide dynamic range ($\sim 10^5$), FID is the detector of choice in cSFC, when normally no organic modifier is used and flow rate after mobile phase expansion is compatible with FID. However, for pSFC, GC detectors usually cannot be used directly due to the large mass flow and the use of combustible organic modifiers. To lower the mass flow, a flow splitter through a restrictor at a ''zero-dead volume'' tee is generally employed,[1] which does not interfere with the back pressure regulators. Two polar modifiers that do not produce FID response are water and formic acid. Use of subcritical water as mobile phase at 80 to 175 °C in the analysis of small alcohol compounds, hydroxyphenols and amino acids with flame ionization detection was reported by Miller and Hawthorne.[17] Other low-pressure detectors commonly used in SFC include the thermionic ionization detector (TID),[43,44] the flame photometric detector (FPD),[45,46] nitrogen–phosphorus detector (NPD),[47,48] the electron-capture detector (ECD),[38,49,50] and the chemiluminescence detector.[51,52]

An alternative universal detector to the FID, which is compatible with mobile phase modifiers, is the evaporative light-scattering detector (ELSD).[53] It is less sensitive and has a narrow dynamic range ($\sim 10^3$). Encouraging results using ELSD in SFC have been reported.[54,55]

UV absorption detectors are the most commonly used detection method in pSFC for analytes with UV-chromophores. However, differing from HPLC, the flow

cell must be capable of withstanding pressures up to 400 bar, because it is placed in-line before the pressure regulator. Other high pressure detection methods that are commonly used in SFC include fluorescence detection. Owing to the high column temperature usually used in SFC, to prevent interference of the UV or fluorescence detection from refractive index fluctuations during the cooling process, a heat exchanger placed before the detector is often used.[1]

Mass spectrometry (MS) affords a highly sensitive and selective means of detection. Numerous methods of coupling SFC to MS have been published.[56–61] Thermospray, electrospray, particle beam and atmospheric pressure chemical ionization (APCI) have attracted the most attention.[51] Atmospheric pressure ionization (electrospray and APCI) is currently undergoing the fastest growth, because it allows independent optimization of SFC and MS.[51]

Other detection methods that are increasingly used in SFC include Fourier transform infrared (FTIR) spectroscopy,[62,63] nuclear magnetic resonance (NMR),[64,65] and electrochemical[66] and amperometric detectors.[67,68]

4 STATIONARY PHASES FOR SUPERCRITICAL FLUID CHROMATOGRAPHY

The stationary phases for cSFC and pSFC are different. The stationary phases in cSFC are often those also used in GC, but they are typically further crosslinked when used for SFC. The film thickness of the stationary phase is typically 0.1 to 3 μm. The most commonly used stationary phases are polysiloxanes.[69] The polarity of the stationary phase is varied by using polysiloxanes with different substituent groups, among which methyl, phenyl and cyano are common choices. Combinations of these groups in different ratios satisfy various polarity needs. For example, dimethylpolysiloxane (100% methyl), phenylmethylpolysiloxane (50% phenyl, 50% methyl), cyanopolysiloxane (100% cyano) and cyanopropylmethylphenylmethylsiloxane are common stationary phases used in cSFC.

The stationary phases for pSFC are similar to those in HPLC. Porous silica is the most common particle for pSFC. The silica packing consists of silica particles (3–10 μm diameter) with 50–500 Å pore sizes and 50–500 $m^2 g^{-1}$ surface area. The polarity of the porous silica is often modified through the attachment of a variety of groups to the organosilane groups. Common functional groups include methyl, phenyl, diphenyl, naphthyl, octadecyl, octyl, diol, cyanopropyl and aminopropyl groups. Unreacted silanol groups are deactivated by end-capping with silylation reagents (e.g. trimethylmethoxysilane). However, residual silanol groups always exist. Active sites on the surface of the particle interact strongly with polar analytes when neat CO_2 is used as the mobile phase, causing poor peak shapes in the chromatogram.[70–73] The addition of polar modifiers into the mobile phase effectively improves the chromatographic band shape as well as lowers the retention of the analyte.[74] Mobile phase modifiers are discussed in detail in the next section. Coating the silica particles with a thin layer of organic polymer is another approach to produce a stationary phase for SFC. Polymer coated silica stationary phases showed improved peak shapes, but still a polar modifier is necessary for effective elution of polar analytes.[1] Totally polymer-based particles, such as those made from polystyrene–divinylbenzene are also used. However, peak tailing is very common with polymeric surfaces as well. In addition, polymer-based particles often swell when exposed to supercritical mobile phases and exhibit less temperature and pressure (mechanical) resistance.[1]

For most of the stationary phases used in pSFC, the apparent mechanism of separation is normal-phase chromatography.[1] For HTLC and EFLC, where CO_2 is not the primary mobile phase, other modes of chromatography, such as reversed-phase, can be easily implemented.

5 MOBILE PHASES FOR SUPERCRITICAL FLUID CHROMATOGRAPHY

5.1 Pure Fluids

Pure fluid mobile phases provide simplicity of operation and often better detector compatibility. Therefore, whenever possible, pure fluids should be considered first. Pure CO_2 is the common first choice. It has been used in the analysis of nonpolar and moderately polar analytes. CO_2 has no permanent dipole moment but has a relatively large quadrupole moment allowing some interactions with polar analytes.[75] CO_2 is suitable for cSFC where a pressure gradient is commonly used to change the retention of solutes. Unlike GC, a temperature gradient is generally not applicable, since under similar pressure, increasing temperature decreases the density and solvent strength of the mobile phase, and therefore increases retention. However, the solvating power of CO_2 is quite limited even under high pressures.

Other pure solvents are also used in SFC. Low-molecular-weight alkanes,[76–78] such as ethane, propane, pentane and hexane, have been used. They exhibit stronger solvent strength than CO_2 and provide different selectivity toward compounds such as polycyclic aromatic hydrocarbons.[71] Their flammability and incompatibility

with FID greatly reduce their popularity. Nitrous oxide has the polarity and critical parameters similar to those of CO_2. It was used in SFC in the early stages of the technique, but no particular advantage was found,[71] while its explosive propensity when used for samples with high organic content[79] deterred further applications.[80] Sulfur hexafluoride is primarily used in the analysis of hydrocarbons.[81] Its compatibility with FID is not as good as carbon dioxide, but it has a wider transparent window for infrared (IR) detection. Trifluoromethane (fluoroform) has a permanent dipole moment and has a lower T_c (26.2 °C) and P_c (48.0 atm) than CO_2.[82] It is also not involved in ozone destruction.[83] It exhibits greater selectivity in the SFC analysis of polycyclic aromatic hydrocarbons than CO_2, nitrous oxide, ethane and $CClF_3$[73] and has stronger eluotropic power than CO_2 and methanol-modified CO_2.[84] The use of other hydrofluorocarbons in SFC is also under study.[85]

The choices for pure polar solvents for SFC are quite limited. Water, despite its unmatched low cost and environmental friendliness, has high critical parameters (374.1 °C and 217.6 atm). Chromatography using subcritical water has been reported.[18] Ammonia, a highly polar solvent with critical temperature and pressure of 132.4 °C and 112.0 atm, has been used as the chromatographic mobile phase in quite a few studies under supercritical or subcritical conditions[4,86,87] as well as for SGC.[24] However, the corrosive and toxic nature prevents it from being widely investigated.

Other than CO_2, none of the pure solvents examined are likely to find wide use. Their applications are preferred only when markedly better selectivity occurs or when CO_2 fails (e.g. because of reactivity toward the sample). Within the foreseeable future, CO_2 and CO_2 with polar modifiers will still dominate the SFC studies.

5.2 Binary or Ternary Mobile Phases

The addition of low percentages (e.g. 1–20%) of polar modifiers into CO_2 is an efficient means to enhance the solvent strength of mobile phase. However, the use of modifiers compromises the compatibility with most GC detectors. For instance, even a small amount of a combustible modifier (e.g. methanol) generates background signal in the FID. Only water and formic acid are exceptions.

The solvent strength enhancement of polar modifiers is disproportionate to its composition in the mixture. For example, the addition of 5% methanol to CO_2 increases the solvent strength to slightly greater than 25% of that of pure methanol.[88] To further improve the solvent strength of the mobile phase or the peak shape of the analyte, a third highly polar component is sometimes added at low concentrations (generally 0.1–1%). For example bases, water, and acids have been added to the modifier to improve performance.

The effects of adding polar modifiers or additives are multifaceted. The modifier can increase the solubility of the analyte, enhance the eluting power of the mobile phase and improve the chromatographic peak shape of the analyte. The solubility enhancement generally follows the solvent strength of the modifier, whereas, other effects depend on the interactions between the mobile phase–solute, mobile phase–stationary phase and solute–stationary phase pairs.[89] For example, the addition of methanol to CO_2 did not improve the elution of chrysene from an octadecylsilyl column, while the same methanol–CO_2 mixtures dramatically decreased the retention factor of chrysene on a sulfonic acid column.[1] The ability of modifiers to improve poor peak shapes is caused by the blocking of ''active sites''[90,91] (residual silanol groups on silica which provide secondary retention mechanisms) on the stationary phase. Other potentially useful interactions between the modifier and the solute include ion-pairing with the analyte[92] and suppression of analyte ionization.[93,94] The mechanism by which the modifier and solute interact is still a controversial issue. As a general rule, additives with similar functionality to the solute are most effective in improving the elution profile.[75]

The addition of modifiers or additives also increases the critical parameters (T_c and P_c) of the resultant mixtures. The degree of change depends on the critical parameters of the modifier or additive and the proportion of modifier added. Methanol–CO_2 mixtures, the most frequently employed system, show moderate increases in T_c and P_c, e.g. CO_2 with 20% methanol exhibits T_c and P_c of 72.2 °C and 76.7 atm, respectively.[95] When binary and ternary mobile phases are used, the chromatographic separation is often actually at subcritical mobile phase conditions.

The phase behavior of the binary or tertiary mobile phase must be known to avoid phase separation in the column and therefore to achieve high efficiency separations. Phase diagrams for commonly used mixtures of mobile phases are available, e.g. methanol–CO_2,[96,97] methanol–CHF_3,[98] methanol–water–CO_2[92,93] and methanol–water–CHF_3,[94] and tetrahydrofuran–CO_2.[99]

Binary and ternary mixtures for SFC can be prepared as premixed or through online mixing. The premixing of solvents provides accurate control of the composition and requires simple chromatographic design. Premixed CO_2 and methanol mixtures or other commonly used modifiers are commercially available in cylinders. However, due to the difference in the vapor pressure of the components, compositional change can occur with usage. For example, a more than twofold change in retention time was reported using premixed methanol–CO_2 throughout the

usage of the cylinder, due to presumably an increase in methanol concentration in the cylinder with time.[100] Online mixing requires two high pressure pumps and accurate control of the delivery ratio from the pumps, but it allows a quick change in modifier concentration and use of a modifier gradient.

Enhanced-fluidity liquids are low viscosity fluids that target the insufficient solvating power of supercritical CO_2 in chromatography and extraction. Instead of adding a polar modifier to CO_2, EFLC adds liquid CO_2 or other low viscosity liquids to common organic solvents.[21,22,101,102] The column pressure is maintained at a value high enough to ensure that the liquid is a single-phase system. The fluidity enhancement observed from the addition of liquid CO_2 to common liquids is significant. For example, by adding 40% CO_2 to methanol the viscosity decreased by approximately 50% while the solvent strength remains similar to that of pure methanol. While most CO_2-based SFC is restricted in normal-phase chromatography, EFLC has been applied to normal,[103] reversed-phase,[22,97] and size-exclusion[95,104] chromatographies. In fact, EFLC can be viewed as bridging the gap between SFC and HPLC.

6 PERSPECTIVES AND FUTURE DEVELOPMENT

Although SFC was first demonstrated in 1960,[105] its major development and recognition of its importance occurred during the early 1990s. Currently, SFC is a standard analytical method alongside GC and LC in many laboratories. It tends to replace normal-phase LC. SFC has found diverse applications in all types of chromatographic analysis traditionally accomplished by GC and HPLC. Numerous reviews and monographs are available on the applications of SFC.[1,2,30,75,106] SFC has been used for the analysis of common chemicals, petroleum-based compounds, pharmaceuticals, food components, natural products, biologically active compounds, agricultural chemicals, synthetic polymers and environmental contaminants.

In the coming years, further applications of analytical and preparative-scale SFC for the separation of chiral pharmaceuticals are expected. Compared to chiral GC, SFC not only extends the sample applicability but also allows separations at lower temperature to prevent potential racemization. For chiral samples amenable to HPLC analysis, SFC provides higher efficiency, a critical parameter in increasing enantiomeric resolution, and shorter analysis time. Enantiomeric separation at cryogenic temperatures using SFC potentiates higher enantiomeric selectivity at much faster speeds compared to HPLC. SFC is also advantageous in preparative chiral separation and solvent removal.

Studies of the mechanism of modifier or additive continue. As the idea of ''unified chromatography'' prevails, more investigations are expected in emerging areas, such as SGC, EFLC and HTLC.

ABBREVIATIONS AND ACRONYMS

APCI	Atmospheric Pressure Chemical Ionization
cSFC	Capillary Supercritical Fluid Chromatography
ECD	Electron-capture Detector
EFLC	Enhanced-fluidity Liquid Chromatography
ELSD	Evaporative Light-scattering Detector
FID	Flame Ionization Detector
FPD	Flame Photometric Detector
FTIR	Fourier Transform Infrared
GC	Gas Chromatography
HPLC	High-performance Liquid Chromatography
HTLC	High-temperature Liquid Chromatography
IR	Infrared
LC	Liquid Chromatography
MS	Mass Spectrometry
NMR	Nuclear Magnetic Resonance
NPD	Nitrogen–Phosphorus Detector
pSFC	Packed Column Supercritical Fluid Chromatography
SFC	Supercritical Fluid Chromatography
SGC	Solvating Gas Chromatography
TID	Thermionic Ionization Detector
UV/VIS	Ultraviolet/Visible

In thin-layer chromatography (TLC), the sample solution is applied as a spot or band on the origin of the layer spread on a support (the plate). After evaporation of the sample solvent, the plate is placed in a sealed chamber containing a solvent chosen as the mobile phase. Development occurs as the mobile phase moves through the layer, and the components of the sample move at different rates to create the separation. The plate is removed from the chamber, and the separated zones are detected by physical or chemical methods, identified by comparison of their migration to standard zones on the same plate, and quantified by visual or instrumental methods based on measurement of zone sizes and intensities. A great variety of compounds can be separated, including organic, inorganic, biological, and chiral. Environmental, pharmaceutical, biomedical, and food samples are among the sample types commonly analyzed by TLC. Advantages of TLC include rapid analysis time because many samples can be analyzed simultaneously, low solvent usage on a per-sample basis, a high degree of accuracy and precision for instrumental TLC, and sensitivity in the nanogram or picogram range. Coupling of TLC with other analytical methods such as high-performance liquid chromatography (HPLC), mass spectrometry (MS), and Fourier transform infrared spectrometry (FTIR) provides enhanced opportunities for sample analysis. Disadvantages of TLC include application to only nonvolatile compounds, limited resolution capability (separation numbers or peak capacities of 10–50), and the absence of fully automated systems, although the individual steps of the technique can be automated.

1 INTRODUCTION

TLC is a type of liquid chromatography in which the stationary phase takes the form of a layer on a glass, aluminum, or plastic support. The term ''planar chromatography'' is often used for both TLC and paper chromatography (PC) because each employs a planar stationary phase rather than a column. PC, which utilizes plain, modified, or impregnated paper (cellulose) as the stationary phase, involves many of the same basic techniques as TLC, but it has not evolved into an efficient, sensitive, quantitative, instrument-based analytical method and has many disadvantages relative to TLC. PC will not be covered in this article.

Originally developed in 1951 by J.G. Kirchner and colleagues, later standardized by E. Stahl and colleagues, and still widely practiced today, classical, capillary-action TLC is an inexpensive, simple method requiring little instrumentation, which is used for separation of simple mixtures and for qualitative identification or semiquantitative, visual analysis of samples. By contrast, modern TLC (usually termed high-performance thin-layer chromatography, HPTLC), which began around 1975 with the introduction by Merck of high-efficiency, commercially precoated plates, is an instrumental technique carried out on efficient, fine-particle layers. HPTLC is capable of producing fast, high-resolution separations and quantitative results with accuracy and precision rivaling those of

gas chromatography (GC) and HPLC. It also has many advantages over these methods.

TLC is an off-line process in which the various stages (Figure 1) are carried out independently. The advantages of this arrangement, using an open, disposable layer compared with an on-line column process such as HPLC, include the possibility of separating up to 70 samples and standards simultaneously on a single plate, leading to high-throughput, low-cost analyses, and the ability to construct calibration curves from standards chromatographed under the same conditions as the samples; analyzing samples with minimum sample preparation without fear of irreversible contamination of the column or carryover of fractions from one sample to another, which can occur in HPLC with sequential injections; and analyzing a sample by use of multiple separation steps and static postchromatographic detection procedures with various universal and specific visualization reagents, which is possible because all sample components are ''stored'' on the layer without chance of loss. TLC is highly selective and flexible because of the great variety of layers that is available commercially. It has proven to be as sensitive as HPLC in many analyses, and solvent usage per sample is extremely low.

TLC and HPTLC plates are usually developed by capillary flow of the mobile phase without pressure in ascending or horizontal modes, but forced flow methods, in which the mobile phase is driven through the layer by pumping under pressure or by centrifugal force, are also used. In capillary flow TLC, the migration speed of the mobile phase decreases with the square of the solvent migration distance.

Limited separation efficiency is a disadvantage of TLC. The maximum number of theoretical plates (N) for HPTLC is around 5000, compared with around 15 000 for HPLC, while the separation number (the number of spots that can be separated over the distance of the run with a resolution of unity) is around 15 in TLC compared with 200 in HPLC. This limited efficiency is a result of the capillary flow mechanism over a restricted migration distance; under forced flow conditions, TLC separation efficiency is significantly improved. An apparent disadvantage of TLC is that, although many of the individual steps have been automated and on-line coupling with other chromatographic and spectrometric techniques has been achieved, complete automation of TLC has not been realized. However, changing the off-line nature of TLC to an on-line closed system with complete automation would eliminate many of the advantages stated above. It has been shown that more samples can be processed with a stepwise automated TLC workstation in an 8 h workday than with a fully automated HPLC system in 24 h.

Analytical TLC differs from preparative layer chromatography (PLC) in that larger weights and volumes of samples are applied to thicker (0.5–2 mm) and sometimes larger layers in the latter method, the purpose of which is the isolation of 10–1000 mg of sample for further analysis.

This article presents the techniques and instrumentation of modern TLC and illustrates how it can complement HPLC and GC in a contemporary analytical laboratory. A reading list is presented at the end from which additional, detailed information on the topics covered, as well as many others, can be obtained.

2 SAMPLE PREPARATION

Sample preparation procedures for TLC are similar to those for GC and HPLC. In order for the solution to be spotted, it must be sufficiently concentrated that the analyte can be detected in the applied volume, and pure enough so that it can be separated as a discrete, compact spot or zone. The solvent in which the sample is dissolved must be suitable in terms of viscosity, volatility, and ability

to wet the layer, and not have the potential for unintended predevelopment during sample application.

Relatively pure samples or their concentrated extracts can often be directly spotted for TLC analysis. If the analyte is present in low concentration in a complex sample, solvent extraction, clean-up (purification), and concentration procedures must precede TLC. Because layers are not reused, it is often possible to apply cruder samples than could be injected into a GC or HPLC column, including samples with irreversibly sorbed impurities. However, impurities that co-migrate with the analyte, adversely affect its detection, or distort its zone (i.e. cause streaking or trailing) must be removed prior to TLC. Carryover of material from one sample to another is not a problem as it is in on-line column methods involving sequential injections, so sample preparation is often simpler for TLC than for these other chromatographic methods.

Common clean-up procedures include liquid–liquid extraction, column chromatography, desalting, and deproteinization. Solid-phase extraction (SPE) using small, disposable columns or membrane disks has recently become widely used for isolation and clean-up of samples prior to TLC analysis. Supercritical fluid extraction (SFE) has been directly coupled to TLC for analysis of solid samples or solutions loaded on glass fiber filters. A derivative of the analyte can be formed in solution prior to spotting, or in situ at the origin by overspotting of a reagent, in order to improve resolution or detection. Special plates with preadsorbent zones serve for sample clean-up by retaining some interfering substances.

3 STATIONARY PHASES

TLC and HPTLC plates are commercially available in the form of precoated layers supported on glass, plastic sheets, or aluminum foil. HPTLC plates are smaller (10×10 cm or 10×20 cm), have a thinner (0.1–0.2 mm) more uniform layer composed of smaller-diameter particles (5–6 μm), and are developed over shorter distances (3–7 cm) compared with classical 20×20 cm TLC plates, which have a 0.25-mm-thick layer of 12–20 μm particle size and are developed for 10–12 cm. Optimal development distances are the point beyond which increased resolution of zones is offset by diffusion effects. Compared with TLC, HPTLC provides better separation efficiency and lower detection limits.

The choice of the layer and mobile phase is made in relation to the nature of the sample. Normal- or straight-phase adsorption TLC on silica gel with a less polar mobile phase, such as chloroform–methanol, is the most widely used mode. Lipophilic C-18, C-8, and C-2 bonded silica gel phases with a polar aqueous mobile phase, such as methanol–water, are used for reversed-phase TLC. Other precoated layers include alumina, magnesium silicate (Florisil), polyamide, cellulose, ion exchangers, and chemically bonded phenyl, amino, cyano, and diol layers. The last three bonded phases can function with multimodal mechanisms, depending on the composition of the mobile phase. Silica gel can be impregnated with various solvents, buffers, and selective reagents to improve separations. Chiral plates composed of a reversed-phase layer impregnated with copper acetate and a chiral selector, (2*S*,4*R*,2′*RS*)-4-hydroxy-1-(2-hydroxydodecyl)proline, can be used to separate enantiomers through a ligand exchange mechanism. Preparative layers are thicker than analytical layers to provide higher sample capacity.

Layers are cleaned by predevelopment with or immersion in methanol prior to sample application, especially for quantitative and preparative applications. The most important manufacturers of TLC plates are Merck, Whatman, Analtech, and Macherey-Nagel, and literature from these companies should be consulted for details of availability, properties, usage, and applications.

4 MOBILE PHASES

Unlike GC, in which the mobile phase (carrier gas) is not a factor in the selectivity of the chromatographic system, the mobile phase in liquid chromatography, including TLC, exerts a decisive influence on the separation. In HPLC, the analyte passes through the on-line detector in the presence of the mobile phase, so solvents must be chosen not only to provide the required resolution but also to not absorb at the ultraviolet (UV) detection wavelength. In TLC the mobile phase is removed (evaporated) before the zones are detected, therefore a wider variety of solvents can be used to prepare mobile phases compared with HPLC.

The mobile phase is usually a mixture of two to five different solvents selected empirically using trial and error guided by prior personal experience and literature reports of similar separations. In addition, various systematic mobile phase optimization schemes involving solvent classification (selectivity) and the elutropic series (strength) patterned after HPLC have been described, most notably the PRISMA model based on Snyder's solvent classification system as developed by Nyiredy. For normal phase (silica gel), the following 10 solvents from Snyder's eight selectivity groups are used for exploratory TLC of the mixture: diethyl ether (group I), isopropanol and ethanol (II), tetrahydrofuran (III), acetic acid (IV), dichloromethane (V), ethyl acetate and dioxane (VI),

toluene (VII), and chloroform (VIII). Hexane (solvent strength = 0) is used to adjust the R_f values within the optimum range (0.2–0.8), if necessary. Between two and five solvents are then selected for construction of the PRISMA model that leads to identification of the optimized mobile phase. A similar procedure is followed for reversed-phase TLC (e.g. C_{18} bonded phase layer) using mixtures of methanol, acetonitrile, and/or tetrahydrofuran with water (solvent strength = 0).

TLC is usually carried out with a single mobile phase, rather than a mobile phase gradient which is often used in HPLC. Equilibration between the mobile phase and the layer occurs gradually during TLC development, and the mobile phase composition can change because different constituents migrate through the layer at different rates (solvent demixing). This leads to solvent gradients along the layer during ''isocratic'' TLC, the formation process of which is very different from the intentional, well-controlled gradients in a fully equilibrated HPLC column. Mobile phase selection for automated multiple development (AMD) will be described below in section 5.

5 APPLICATION OF SAMPLES AND STANDARDS

Application of small, precisely positioned initial zones from sample and standard solutions without damaging the layer surface is critical for achieving maximum resolution and reliable quantitative analysis. The volumes applied and the method of application depend on the type of analysis to be carried out (qualitative or quantitative), the layer (TLC or HPTLC), and the detection limit.

5.1 Sample Application as Spots

For TLC, 0.5- to 5-μL volumes are usually applied manually with a micropipet to produce initial zones with diameters in the 3–4 mm range. For HPTLC, initial zones in the form of spots with a maximum diameter of 1–2 mm are applied from a 100-nL to 1-μL fixed-volume, self-loading glass capillary pipet, which is held in a rocker-type mechanized spotting device (the Nanomat) that mechanically controls its positioning and brings the capillary tip into gentle and uniform contact with the layer to discharge the solution without damaging the layer. The volume precision of this applicator is below 1% (relative standard deviation, RSD). Variable volumes can be applied with a micrometer-controlled syringe.

5.2 Sample Application as Bands

Sample application in the form of bands is advantageous for high-resolution separations and precise (1% RSD) quantitative scanning densitometry using the aliquot technique (scanning with a slit of one-half to two-thirds the length of the applied band). Narrow, homogeneous sample bands of controlled length [1 mm (spot) to 190 mm] can be applied by use of a spray-on device (the Linomat) in which the plate is mechanically moved right to left in the x-direction beneath a fixed syringe from which 2–100 μL of sample (5–490 μL for preparative separations) is sprayed by an atomizer operating with a controlled nitrogen gas pressure. The bands are exactly positioned according to a coordinate system, which facilitates automated scanning after chromatogram development, or overspraying of samples with a reagent for in situ prechromatographic derivatization or with spiking solutions for validation of quantitative analysis by the standard-addition method. The ability to apply larger volumes to an HPTLC plate without loss of resolution lowers the determination limits with respect to the concentration of the solution, which aids in trace analysis. Complex, impure samples can often be successfully quantified, but only if bands are applied rather than spots.

In addition to band formation by instrumental means, sharp bands are also produced when samples are applied manually with a micropipet as diffuse vertical streaks to special plates containing a preadsorbent or concentrating zone. These plates, as well as the Linomat, facilitate quantitative analysis by allowing different volumes of the same standard solution to be applied to produce the densitometric calibration curve, rather than the same volume of a series of standards when spots are applied.

5.3 Automated Sample Application

Figure 2 shows the Automatic TLC Sampler III, which is a fully automated, computer-controlled device for sequential application of samples and standards from a rack of vials through a steel capillary as spots by contact transfer or as bands by a spray-on technique. The speed, volume, and pattern of standard and sample application are controllable, and a programmable rinse cycle can eliminate cross-contamination. Analyses performed with this applicator combined with densitometric chromatogram evaluation controlled by the same computer conform to good laboratory practice (GLP) and good manufacturing practice (GMP) standards.

6 CHROMATOGRAM DEVELOPMENT

Development times are typically in the range of 3–60 min, depending on the layer, mobile phase, and development method chosen. However, development time does not significantly influence the overall analysis time per

Figure 2 Automatic TLC Sampler. (Photograph supplied by D. Jaenchen, Camag, Muttenz, Switzerland.)

sample because many samples and standards can be chromatographed simultaneously.

6.1 Capillary Flow Thin-layer Chromatography

6.1.1 Ascending Development

The results of TLC are strongly dependent upon the environmental conditions during development, such as small changes in mobile phase composition, temperature, humidity, and the size and type of the chamber and its solvent vapor saturation conditions.

In the classical method of linear, ascending development TLC and HPTLC, the developing solvent is contained in a large-volume, covered glass tank (N-tank). The spotted plate is inclined against an inside wall of the tank with its lower edge immersed in the developing solvent below the starting line, and the solvent begins to rise immediately through the initial zones because of the capillary flow. As the mobile phase ascends, the layer interacts with the vapor phase in the tank. The space inside the tank is more or less equilibrated with solvent vapors, depending on the presence or absence of a mobile phase-soaked paper liner and the period of time the tank is allowed to stand before the plate is inserted. The use of a paper liner to provide saturation of the tank atmosphere with solvent vapors can be advantageous or detrimental, depending on the composition of the mobile phase.

More reproducible conditions can be established in an S-chamber (sandwich chamber), which consists of the TLC plate, a spacer of 3 mm thickness, and a cover- or counter-plate that is either blank glass or a solvent-soaked TLC plate. These parts are clamped together, so that the bottom 2 cm of the layer is uncovered, and are placed in a trough containing the mobile phase. Interaction between the layer, dry or wetted, and the gas phase is largely suppressed in an S-chamber, and reproducibility of the separation is improved.

The twin-trough chamber is an N-chamber modified with an inverted V-shaped ridge on the bottom dividing the tank into two sections, which allow development with only 4–20 mL of solvent, depending on the plate size, on one side, and easy pre-equilibration of the layer with vapors of the mobile phase or another conditioning liquid (e.g. a sulfuric acid–water mixture to control humidity) or volatile reagent on the other side.

A computer-controlled automatic developing chamber has been designed to provide reproducible isocratic one-dimensional (1-D) ascending development without operator attention. Parameters for preconditioning, N- or S-tank configuration, solvent migration distance, and drying with filtered cold or heated air are programmable via a key pad. The developing process is monitored, and elapsed time and running distance are continually displayed. Ten complete developing programs can be stored in computer memory.

6.1.2 Horizontal Development

The horizontal developing chamber permits simultaneous development from opposite edges to the middle of 60 sample spots on a 20×10 cm HPTLC plate, or 30 samples from one end to the other. The developing solvent, held in narrow troughs, is carried to the layer through capillary slits formed between the trough walls and glass slides. The chamber is covered with a glass plate during pre-equilibration and development and can be operated in N-type or S-type configurations, including humidity control by placing an appropriate sulfuric acid–water mixture in a conditioning tray. Use of the horizontal developing chamber allows separation conditions to be efficiently standardized, and only low amounts of mobile phase are required.

6.1.3 Continuous Development

The short bed continuous development (SB/CD) chamber is used for continuous development, which leads to

improved resolution of zones with low migration rates because of the larger effective separation distance. Four glass ridges and the back wall of the chamber support the plate at five different angles of inclination, each of which allows increasing lengths of the layer to protrude out of the top of the chamber. Solvent continually evaporates from the external layer at the top and is replaced by additional solvent drawn from the chamber at the bottom.

6.1.4 Gradient Elution Thin-layer Chromatography Combined with Automated Multiple Development

AMD generally involves 10–30 individual linear ascending developments of an HPTLC plate (usually silica gel) carried out in an AMD instrument, which includes an N-type chamber equipped with connections for feeding and releasing mobile phase and pumping a gas phase in and out, storage bottles for pure solvents and waste, a gradient mixer, syringes for measuring solvent volumes, and sensors for measuring migration distances. The developments are performed in the same direction with a stepwise mobile phase gradient that becomes progressively weaker (i.e. less polar) over distances that increase by 1–5 mm for each stage. The solvent is completely removed from the chamber and the layer is dried under vacuum applied by a pump for a preselected time after each development. The layer is then preconditioned with the vapor phase of the next batch of fresh solvent, which is fed into the chamber before the next incremental run.

The solvent strength may be changed for each development, or several stages may be carried out with the same solvent before changing its strength. The repeated movement of the solvent front through the chromatographic zones causes them to become compressed into narrow bands (width about 1 mm) during AMD, leading to peak capacities of more than 50 over a separation distance of 80 mm. Typical ''universal gradients'' for AMD are produced from methanol or acetonitrile (polar), dichloromethane, diisopropyl ether or *tert*-butylmethyl ether (medium polarity) and hexane (nonpolar). The central or basis solvent and the nonpolar solvent have the greatest effect on selectivity. By superimposing the densitogram of a chromatogram with a matched-scale diagram of the gradient, required modifications of the solvent system can be predicted.

Complex mixtures containing compounds with widely different polarities can be separated by AMD on one chromatogram, in which sharply focused zones migrate different distances according to their polarities. Zone widths are independent of migration distance and size of the starting zone, leading to high resolution and the ability to resolve relatively large samples for trace analysis. Migration distances of individual components are largely independent of the sample matrix, and detection limits are improved because of the highly concentrated zones that are produced.

Figure 3 Densitogram of 11-component mixture of saccharides (230–500 ng) separated by AMD on a phosphate-buffered amino-bonded silica gel layer using an acetonitrile–acetone–water gradient (30:30:40 to 20:15:65 v/v/v) and 15 development steps of increasing length. 1, maltohexose; 2, maltopentose; 3, maltotetrose; 4, maltotriose; 5, maltose; 6, sucrose; 7, glucose; 8, fructose; 9, xylose; 10, rhamnose; 11, desoxyribose. (Photograph supplied by D. Jaenchen, Camag, Muttenz, Switzerland.)

Figure 3 illustrates a densitometer scan of a chromatogram produced by gradient AMD.

6.1.5 Two-dimensional Development

Two-dimensional (2-D) TLC involves spotting the sample in one corner of the layer, developing (ascending or horizontal) with the first mobile phase, drying the plate, and developing at a 90° angle with a second mobile phase having a diverse, complementary separation mechanism (selectivity). Computer simulation has been used to optimize 2-D separations based on 1-D data. Resolution (spot capacity) in 2-D TLC is greatly improved compared with 1-D TLC because sample components are resolved over the entire area of the layer, and is usually superior to that obtained by HPLC. Resolution by 2-D forced flow planar chromatography (FFPC) (see below) exceeds 2-D capillary flow TLC because spot diffusion is smaller. Disadvantages of 2-D TLC include a limit of one sample per plate and the time required for two developments and intermediate drying. In addition, quantitative calibration or qualitative identification standards cannot be developed in parallel on the same plate at the same time. Improved video densitometers may allow more reliable quantitative 2-D TLC in the future than is possible today with the commonly used slit-scanning densitometers.

6.2 Forced Flow Planar Chromatography

The mobile phase can migrate through the layer by capillary action, as is the case in the procedures described above, or under the influence of forced flow. FFPC has theoretical advantages relative to capillary flow, including independent optimization of mobile-phase velocity, higher efficiency, lower separation time, and use of solvents that do not wet the layer, but it requires specialized, complex commercial instrumentation. Forced flow is produced by mechanically pumping solvent through a sealed layer (overpressured layer chromatography, OPLC) or by spinning a glass rotor covered with sorbent around a central axis to drive the solvent from the center to the periphery of the layer by centrifugal force (rotation planar chromatography, RPC). Separations can be accomplished with a dry layer (off-line FFPC), but the closed system arrangement also allows the separation to be started after the layer is equilibrated with the mobile phase, similar to the situation in HPLC (on-line FFPC).

In RPC, samples are applied to the rotating stationary phase near the center, and centrifugal force plus capillary action drives the mobile phase through the sorbent from the center to the periphery of the plate. Up to 72 samples can be applied for analytical separations, and in situ quantification is possible. One circular sample is applied for micropreparative and preparative separations, which can be carried out off- and on-line. Various chambers are used for RPC, which differ mainly in the volume of the vapor space. The major commercial instruments for RPC are the Chromatotron 7924, CLC-5, and Rotachrom Model P. Although analytical applications have been proposed, RPC appears to be most useful for preparative applications.

OPLC combines many advantages of classical TLC and HPLC. Two commercial development chambers available for OPLC are the Chrompres 10 and Chrompres 25, which operate at pressures up to 10 and 25 atm respectively. The higher pressure of the Chrompres 25 allows the use of more viscous mobile phases and/or higher mobile phase velocities in the linear development mode. The chambers consist of a bottom support block and an upper block with a poly(methyl methacrylate) support plate, fixed in an external frame. The plate is placed on the surface of the bottom block, and the chamber is closed. A pump produces a water cushion against a flexible plastic membrane, which covers the layer and eliminates any vapor space, resulting in more reproducible separations under controlled conditions. A second pump forces mobile phase through the layer at a constant flow rate in the range of $1-12\,\mathrm{mL\,min^{-1}}$, leading to higher separation efficiency than is possible with capillary flow. A mobile-phase outlet is located in the upper block. To carry out linear chromatography, the layer must be specially prepared by scraping the edges and treating with a polymer sealant to eliminate leaks during development, and by cutting mobile-phase inlet and solvent outlet channels at appropriate positions. The Chrompres instruments allow linear development distances of 18 or 36 cm on a 20×40 cm TLC plate in the on-line mode, plus off-line circular development, for which no plate preparation is required for a maximum separation distance of 9 cm. Special plate preparation is required for circular or anticircular development over longer distances. Linear and circular OPLC are suitable for development of several plates simultaneously (parallel connected OPLC), or serial combination of plates is possible (long-distance OPLC). Different types of layers can be employed for a single analysis in these multilayer OPLC methods. The Personal OPLC BS 50 is a newer commercial OPLC instrument. Although OPLC has been the most used FFPC method, its reported practical applications have been quite limited.

High-pressure planar liquid chromatography (HPPLC) is a radial OPLC method that has been described but not widely used because of the unavailability of a commercial instrument. A single sample is applied to the center of the layer, and the mobile phase is delivered to the same point using up to 200 bar external pressure. In-flow sample injection is also possible. The method allows transfer of capacity factor (k') data to HPLC as well as coupling of HPLC and planar chromatography.

7 ZONE DETECTION

After development with the mobile phase, the plate is dried in a fumehood and heated to completely evaporate the mobile phase. Separated compounds are detected on the layer by their natural color, natural fluorescence, quenching of fluorescence, or as colored, UV-absorbing, or fluorescent zones after reaction with an appropriate reagent (post-chromatographic derivatization). Although dependent upon the particular analyte and the detection method chosen, sensitivity values are generally in the nanogram range for absorbance and picogram range for fluorescence.

Layers are frequently heated after applying the detection reagent in order to accelerate the reaction upon which detection is based. Heating is carried out with a hair drier in a fumehood, in an oven, or with a TLC plate heater. The plate heater, which contains a 20×20 cm flat, even heating area, a grid to facilitate proper positioning of TLC and HPTLC plates, programmable temperature between 25 and 200 °C, and digital display of the actual temperature, provides the most consistent heating conditions.

Compounds that are naturally colored are viewed directly on the layer in daylight, while compounds with

native fluorescence are viewed as bright zones on a dark background under UV light. Viewing cabinets incorporating shortwave (254 nm) and longwave (366 nm) UV lamps are available for inspecting chromatograms in an undarkened room.

Compounds that absorb around 254 nm, particularly those with aromatic rings and conjugated double bonds, can be detected on an ''F-layer'' containing a phosphor or fluorescent indicator (often zinc silicate). When irradiated with 254 nm UV light, absorbing compounds diminish (quench) the uniform layer fluorescence and are detected as dark violet spots on a bright background.

Universal or selective chromogenic and fluorogenic liquid detection reagents are applied by spraying or dipping the layer. Various types of aerosol sprayers and dip tanks are available for manual operation. For safety purposes, spraying is carried out inside a laboratory fumehood or commercial TLC spray cabinet with a blower (fan) and exhaust hose. Dipping is usually the best method for reproducible results, and the most uniform dip application of reagents can be achieved by using a battery-operated chromatogram immersion instrument, which provides selectable, consistent vertical immersion and withdrawal speeds of 30–50 mm s^{-1} and immersion times of 1–8 s for plates with 10 or 20 cm heights. This mechanized dipping device can also be used for prewashing TLC plates prior to initial zone application, impregnation of layers with reagents that improve resolution or detection prior to initial zone application and development, and for postdevelopment impregnation of chromatograms containing fluorescent zones with a fluorescence enhancer and stabilizer, such as paraffin. A few detection reagents (HCl, sulfuryl chloride, iodine) can be transferred uniformly to the layer as vapors in a closed chamber.

8 DOCUMENTATION OF CHROMATOGRAMS

TLC separations are best documented by photography or video recording. Commercial systems for photodocumentation contain instant and conventional film cameras and associated lighting accessories for photography of colored, fluorescent, and fluorescence-quenched zones on TLC plates in shortwave, midrange, and longwave UV light and in visible light. A commercial video documentation system includes visible and UV lighting, a video or digital camera with zoom lens, monitor, and video printer. The system can also be extended to include data storage on a personal computer. A cabinet is available to house the photographic and video instruments for use in an undarkened room.

The latest technology for documentation of TLC plates involves computer scanning of the spots on the plate. The equipment required includes a computer, scanner, and monochrome or color printer. Computer scanning can be used only for visible spots, and not for those that are fluorescent or quench fluorescence.

9 ZONE IDENTIFICATION

The identity of TLC zones is obtained in the first instance by comparison of R_f values between samples and reference standards chromatographed on the same plate, where R_f equals the migration distance of the center of the zone divided by the migration distance of the mobile-phase front. Identity is more certain if a selective chromogenic reagent yields the same characteristic color for sample and standard zones, or if an R_f match is obtained in at least two TLC systems with diverse mechanisms, e.g. silica gel normal phase and C-18 bonded silica gel reversed-phase. Comparison of standard and sample in situ ultraviolet/visible (UV/VIS) absorption or fluorescence emission spectra, obtained by using the spectral mode of a densitometer, can also aid identification, but these spectra often contain inadequate structural information for complex mixtures. Identity can be confirmed by application of combined TLC-spectrometry methods described in section 11.1.

10 QUANTITATIVE ANALYSIS

10.1 Nondensitometric Methods

Quantification of thin-layer chromatograms can be performed after manually scraping off the separated zones of samples and standards and elution of the substances from the layer material with a strong, volatile solvent. The eluates are concentrated and analyzed by use of spectrometry, GC, HPLC, or some other sensitive microanalytical method. This method of quantification is laborious and time-consuming, and the difficulty in recovering samples and standards uniformly is a major source of error. Although its importance has declined relative to densitometry, the indirect scraping and elution quantification method is still widely used, e.g. for some drug assays according to the US Pharmacopoeia.

Direct TLC semiquantitative analysis can be performed by visual comparison of sample spot intensities with the intensities of reference spots developed simultaneously on the same layer. For this comparison, the bracketing method is used in which standard spots with concentrations equal to, greater than, and less than the expected

sample concentration are placed on either side of duplicate sample spots. The concentrations of samples and standards should lie within the linear response range of the detection method. The use of TLC for compliance screening of drug products is an important example of this approach.

10.2 Densitometric Evaluation

Most modern HPTLC quantitative analyses are performed by in situ measurement of the absorbance or fluorescence of the separated zones in the chromatogram tracks using an optical densitometic scanner with a fixed sample light beam in the form of a rectangular slit. The length and width of the slit are selectable for optimized scanning of zones with different dimensions. The densitometer measures the difference between the optical signal from a zone-free background area of the plate and from the calibration standards and sample zones. With automated zone application, precision ranging from 1% to 3% RSD is typical for densitometric analyses.

The plate is mounted on a moveable stage controlled by a stepping motor, which allows each chromatogram to be scanned, usually in the direction of development. Single-beam geometry is most often used and gives excellent results when high-quality plates and mobile phase produce compact, well-separated zones. A schematic diagram of a single-beam scanner arranged for measurement of absorption in the reflectance mode is shown in Figure 4. A tungsten–halogen lamp is used as the source for scanning colored zones in the 400–800 nm range (visible absorption) and a deuterium lamp for scanning UV-absorbing zones directly or as quenched zones on F-layers in the 190–400 nm range. The monochromator used with these continuous wavelength sources can be a quartz prism or, more often, a grating. The detector is a photomultiplier or photodiode. For fluorescence scanning, a high-intensity xenon or mercury vapor lamp is used as the source, the optimum excitation wavelength is selected by the monochromator, and

Figure 4 Schematic diagram of the optical path of commercially available densitometers for absorption scanning. R, recorder; I, integrator; PM, photomultiplier detector; P, plate; S, mirror; MC, monochromator; W, tungsten incandescent lamp; D, deuterium lamp; M, mercury lamp.

a cut-off filter is placed between the plate and detector to block the exciting UV radiation and transmit the visible emitted fluorescence. Simultaneous measurement of reflection and transmission, or transmission alone, can be carried out by means of a second detector positioned on the opposite side of the plate. Ratio-recording double-beam scanners, which can correct for background disturbances and drift caused by fluctuations in the source and detector, are equipped with a chopper to alternate the light beam between sample and reference paths before reaching the detector (double beam in time). For dual-wavelength, single-beam scanning, which will correct for matrix scattering of the absorbed light by subtracting out the (presumably equal) scattering at a nonabsorbed wavelength, a light beam is selected by a mirror and passes through two separate monochromators to isolate the two different wavelengths. The two beams are alternated by a chopper and recombined into a single beam representing a difference signal at the detector. Zig-zag scanning with a small spot of light is possible with scanners that have two independent stepping motors to move the plate in the x- and y-axes. Computer algorithms integrate the maximum absorbance measurements from each swing, which corresponds to the length of the slit, to produce a distribution profile of zones having any shape. Disadvantages of scanning with a moving light spot include problems with data processing, lower spatial resolution for HPTLC, and unfavorable error propagation. Some densitometers have the ability to rotate the plate while scanning for measurement of circular and anticircular chromatograms.

Most modern scanners have a computer-controlled motor-driven monochromator that allows automatic recording of in situ absorption and fluorescence excitation spectra. These spectra can aid compound identification by comparison with co-chromatographed standards or stored standard spectra, can test for identity by superimposition of spectra from different zones on a plate, and check zone purity by superimposition of spectra from different areas of a single zone. The spectral maximum determined from the in situ spectrum is usually the optimal wavelength for scanning standard and sample areas for quantitative analysis.

The scanner is connected to a recorder, integrator, or computer. A computer with software designed specifically for TLC is most common for data processing and automated control of the scanning process in modern instruments. With a fully automated system, the computer can carry out the following functions: data acquisition by scanning all plate tracks following a preselected geometric pattern with control of all scanning parameters; automated peak searching and optimization of scanning for each fraction located; multiple wavelength scanning to find, if possible, a common wavelength at which all substances can be quantified or the wavelength of maximum absorbance

of each compound, to optically resolve fractions incompletely separated by TLC, and to identify fractions by comparison with stored data through pattern recognition; baseline location and correction; computation of peak areas and/or heights of samples and co-developed standards and processing of the analog raw data to quantitative digital results, including calculation of calibration curves by linear or polynomial regression, interpolation of sample concentrations, statistical analysis of reproducibility, and presentation of a complete analysis report; and storage of raw data on disk for later reintegration, calibration, and evaluation with different parameters.

Because of light scattering from the sorbent particles, a simple, well-defined mathematical relationship between the amount of analyte and the light signal has not been found. Curves relating absorption signal (peak height or area) and concentration or weight of standards on the layer are usually nonlinear, especially at higher concentrations, and do not pass through the origin. Modern integrators and computer software programs can routinely perform linear or polynomial regression of the calibration data, depending on which is most suitable. Fluorescence calibration curves are generally linear and pass through the origin, and analyses based on fluorescence are more specific and 10–1000 times more sensitive than those employing absorbance. Because of these advantages, compounds that are not naturally fluorescent are derivatized before or after chromatography to allow them to be scanned in the fluorescence mode if an appropriate reagent is available. However, absorbance in the 190–300 nm UV range has mostly been used for densitometric analyses.

Validation procedures for quantitative analysis are in some aspects very similar to those for HPLC and GC, with additional considerations related to procedural aspects specific to TLC. Protocols for validation of TLC results, especially for pharmaceutical analysis, are available in the literature. Some densitometers include automatic instrument validation programs in their software.

Video densitometers (image processors) are an alternative to the optical/mechanical scanners. Video densitometry is based on electronic point-scanning of a stationary plate using an instrument composed of UV and visible light sources, a charge coupled device (CCD) camera with zoom capabilities, and a computer with imaging and evaluation software. Video scanners have advantages including rapid data collection and storage, simple design with virtually no moving parts, easy operation, and the ability to quantify 2-D chromatograms, but they have not yet been shown to have the required capabilities to replace slit scanning densitometers. Current video scanners can function only in the visible range to measure colored, fluorescence quenched, or fluorescent spots. They lack the spectral selectivity and accuracy based on the ability to scan with monochromatic light of selectable wavelength throughout the visible and UV range (190–800 nm) that is inherent in classical densitometry, and they cannot record in situ spectra.

11 SPECIAL TECHNIQUES

11.1 Thin-layer Chromatography Combined with Spectrometric Methods

11.1.1 Mass Spectrometry

The identity of TLC zones can be confirmed by MS analysis. A zone can be scraped out of the layer, eluted from the sorbent, and transferred to the mass spectrometer as a discrete sample. Alternatively, the sample is not separated from the scraped sorbent and both are introduced into the spectrometer source on a direct insertion probe. Desorption methods include volatilization from a heated probe tip, laser ablation, or particle beam sputtering. Ionization techniques that have been used are electron impact (EI) for stable, volatile analytes, while less volatile or unstable analytes can be ionized by chemical ionization (CI), secondary ion mass spectrometry (SIMS), fast atom bombardment (FAB) or liquid secondary ion mass spectrometry (LSIMS) after mixing the sorbent with a suitable liquid matrix (e.g. glycerol). An alternative instrumental approach uses probes or plate scanners specifically designed to measure separated TLC zones. A sophisticated device for 2-D imaging of TLC plates using LSIMS has been described, as well as applications of TLC/tandem MS (TLC/MS/MS) to a variety of compound classes.

11.1.2 Infrared Spectrometry

Zones can also be confirmed by combining TLC with FTIR. Transfer techniques involve solvent extraction of the zone from the layer to an infrared (IR)-transparent pellet or powder (KBr). The most common in situ method is diffuse reflectance infrared detection (DRIFT), which has been used with silica, alumina, cellulose, and reversed-phase layers for identifications at the 1 μg level. Background absorption by the sorbent (3700–3100 and 1650–800 cm^{-1} for silica gel) must be subtracted from the sample spectrum; the resulting difference spectrum of the analyte may not match a solution spectrum in terms of absorption band positions and shapes because of interactions between the compound and sorbent. Sensitivity limits are high (ca. 1–10 μg per spot), but quantification is possible for compounds that do not absorb UV radiation or are not detectable by derivatization reagents.

11.1.3 Raman Spectrometry

In situ normal Raman spectrometry (RS) has a relatively high sensitivity of around 0.5–10 μg for measurement of zones on a TLC plate, but spectra resemble those measured on solids in published collections and are suitable for identification of unknown substances.

Surface enhanced Raman spectrometry (SERS) has sensitivity in the nanogram or picogram range. The layer is treated with a colloidal silver solution, and it is then excited with an Ar-ion or He–Ne laser. Unknown spectra must be compared to a collection of spectra of reference compounds measured on similar layers in the user's laboratory.

11.1.4 X-ray Fluorescence Spectrometry

TLC and X-ray fluorescence spectrometry (XRF) have been combined without an interface to provide direct, nondestructive visualization of elements in zones on the layer. Precoated silica gel and cellulose plates were developed, dried, wrapped in polyethylene film, and taped onto the sample stage of an X-ray analytical microscope equipped with an unfiltered Rh-target X-ray guide tube having an aperture set to analyze a spot around 100 μm in diameter. Longitudinal scanning obtains the elemental image along the length of the chromatogram.

TLC/XRF has been applied to the detection of inorganic metal ions, organometallics (porphyrins), halogens in pesticides and related compounds, and P and S in nucleotides and amino acids, respectively. Organic compounds containing electronegative elements can be selectively detected by individual elemental imaging, such as phenols containing chlorine, bromine, or iodine. Minimum detectable element concentrations ranged from 1 to 200 nmol μL^{-1} spotted (0.13–25 nmol mm^{-2} of layer surface).

11.2 Direct Coupling of Thin-layer Chromatography and High-performance Liquid Chromatography

TLC and HPLC can be combined into a powerful multidimensional method with enhanced separation efficiency because the former is generally used with a normal phase mechanism and samples are separated by distance, while the latter is most often reversed-phase and samples are separated by time. On-line coupling is possible by depositing HPLC column effluent onto the surface of a moving plate. The deposited HPLC fractions serve as the origin for further TLC separation with different selectivity.

The amount of HPLC effluent reaching the plate must be minimized so that overloading does not reduce resolution and the layer material is not washed away. This is done by using effluent-splitting or microbore columns coupled with a solvent elimination interface. The Linomat and Automatic TLC Sampler (section 5) have been modified and connected to the column outlet for spray-on application of HPLC effluent. With the combination of HPLC and TLC/AMD, peak capacities of around 500 can be accomplished.

HPLC and TLC have been coupled with spectrometric methods to achieve powerful detection and identification systems. Methods combined with HPLC/TLC have included FTIR, SERS, and fluorescence spectrometry. TLC has been interfaced on-line with GC, supercritical fluid chromatography (SFC), and high-speed countercurrent chromatography in a manner analogous to HPLC.

11.3 Thin-layer Radiochromatography

Location and quantification of separated radioisotope-labeled substances on a thin layer requires the use of autoradiography, zonal analysis, or direct scanning with a radiation detector.

Autoradiography involves exposure of X-ray or photographic film to emissions from radioisotope zones to produce an image on the film. After exposure and development of the film, the radioisotopes are visible as dark spots, which can be quantified by measurement of their optical densities with a scanning densitometer.

Zonal analysis involves scraping radioactive zones from the plate, placing the sorbent in counting vials, adding scintillation fluid or cocktail to elute the radioactive components, and liquid scintillation counting.

The first radiation detectors for direct measurement of radioactivity on TLC plates were the radioscanners, which utilized a mechanically driven windowless gas-flow Geiger counter. Linear analyzers are superior to radioscanners because the components of one entire track of the plate can be simultaneously measured without mechanical scanning, and the instrument can be programmed to move the detector head automatically to any chosen position. Linear analyzers incorporate a position-sensitive windowless gas-flow proportional counter as the detector. The fill gas (e.g. argon–methane) is ionized when radioactive emissions from the TLC zones enter the detector, producing electrons. The electron pulses are detected electronically and stored in computer memory to provide a digital image of the distribution of radioactivity on the layer. Multiwire proportional counters (Digital Autoradiograph or microchannel array detector) are 2-D detectors based on a measuring principle similar to the linear analyzer, but they can detect all areas of radiation from a 20×20 cm layer simultaneously without moving a detector head. Bioimaging/phosphor imaging analyzers represent the latest and most advantageous technology for measuring radioactive TLC zones. The layer is exposed to a phosphor imaging plate that accumulates and stores irradiating radioactive energy from the zones.

The plate is then inserted into an image-reading unit and scanned with a fine laser beam. Luminescence is emitted in proportion to the intensity of the recorded radiation, collected by a photomultiplier tube, and converted to electrical energy to produce an instrumental readout. Resolution, linear range, and sensitivity are equal to, or better than, those of the other detection methods.

Thin-layer radiochromatography is especially important in drug and pesticide metabolism studies in plants, animals, and humans and in studies of the fate of labeled chemicals in the environment. The methods described above are mainly for qualitative detection, but some degree of quantitative information can be obtained.

11.4 Rod Thin-layer Chromatography with Flame Ionization Detection

Separation on thin, cylindrical quartz rods coated with sintered silica gel (Chromarods) has been combined directly with flame ionization detection (FID) for analysis of compounds lacking a chromophore functional group that can facilitate optical densitometry, such as hydrocarbons and lipids. The sample is applied to the bottom of the rod, and several rods are placed in a support frame, then the frame is placed in a development chamber. After development, solvent is removed from the rods by oven drying, and individual rods are automatically passed through the detector at constant speed. The organic compounds separated on the rods are ionized by the flame of the FID, and the ions generate an electric current proportional to the amount of each compound. The data obtained are processed in a manner similar to GC with the same detector.

12 APPLICATIONS OF THIN-LAYER CHROMATOGRAPHY

TLC can provide rapid, low-cost qualitative analyses and screening in order to obtain information, such as sample stability, purity, and uniformity, and to follow the course of a reaction, while instrumental HPTLC can provide accurate and reproducible (1–3% RSD) quantitative results. Samples that are difficult to prepare can be analyzed readily, and detection is especially flexible in the absence of the mobile phase and with a variety of parameters.

TLC has been applied in virtually all areas of analysis, including chemistry, biochemistry, biology, industry, agriculture, environment, food, pharmaceuticals, clinical studies, natural products, toxicology, forensics, plant science, bacteriology, parasitology, and entomology. Compound types to which TLC has been successfully applied include pharmaceuticals and drugs, neutral and polar lipids, organic acids, carbohydrates, amino acids, peptides, phenols, indoles, purines, steroids, synthetic and natural dyes, vitamins, inorganics, and chiral compounds. High and low (trace) levels of analytes can be detected, identified, and quantified.

Discussion of specific applications of TLC is beyond the scope of this article. The reading list provides sources of information on the analysis of all types of compounds and samples, as well as discussions on theory, techniques, and instrumentation. Especially recommended for information on applications are the Sherma–Fried *Handbook of Thin Layer Chromatography*, the Fried–Sherma *Practical Thin Layer Chromatography* book, the biennial reviews by Sherma in *Analytical Chemistry*, and the Camag "CBS". The *Journal of Planar Chromatography–Modern* TLC, published in six issues per year by the Research Institute for Medicinal Plants (Budakalasz, Hungary) in cooperation with Springer Hungarica, Budapest, exclusively features research papers, short communications, and reviews in the fields of analytical and preparative TLC and HPTLC.

ABBREVIATIONS AND ACRONYMS

AMD	Automated Multiple Development
CCD	Charge Coupled Device
CI	Chemical Ionization
DRIFT	Diffuse Reflectance Infrared Detection
EI	Electron Impact
FAB	Fast Atom Bombardment
FFPC	Forced Flow Planar Chromatography
FID	Flame Ionization Detection
FTIR	Fourier Transform Infrared Spectrometry
GC	Gas Chromatography
GLP	Good Laboratory Practice
GMP	Good Manufacturing Practice
HPLC	High-performance Liquid Chromatography
HPPLC	High-pressure Planar Liquid Chromatography
HPTLC	High-performance Thin-layer Chromatography
IR	Infrared
LSIMS	Liquid Secondary Ion Mass Spectrometry
MS	Mass Spectrometry
OPLC	Overpressured Layer Chromatography
PC	Paper Chromatography
PLC	Preparative Layer Chromatography
RPC	Rotation Planar Chromatography
RS	Raman Spectrometry
RSD	Relative Standard Deviation
SB/CD	Short Bed Continuous Development
SERS	Surface Enhanced Raman Spectrometry
SFC	Supercritical Fluid Chromatography

SFE	Supercritical Fluid Extraction
SIMS	Secondary Ion Mass Spectrometry
SPE	Solid-phase Extraction
TLC	Thin-layer Chromatography
UV	Ultraviolet
UV/VIS	Ultraviolet/Visible
XRF	X-ray Fluorescence Spectrometry
1-D	One-dimensional
2-D	Two-dimensional

1 INTRODUCTION

Mass spectrometry (MS) is the study of matter through the determination of the abundance and the mass-to-charge ratio (m/z) of ions in the gas phase. The data of MS are mass spectra. The mass spectrum is a plot of relative intensities (which represent the ion abundances) on the ordinate versus the m/z values of the ions on the abscissa. The tools of MS are mass spectrometers. A mass spectrometer consists of a sample-inlet system, a device for getting ions into the gas phase (the ion source), a method of separating the ions according to their m/z values (the m/z or mass analyzer), and a means of detecting the ions after they have been separated (the detector). The ions are separated and detected in the absence of other substances (i.e. in a high vacuum). Therefore, another significant component of a mass spectrometer is the vacuum system (Figure 1). In the mass spectrometers of the latter half of the 20th century and those of the 21st century, sample introduction, ionization, ion separation and detection, and data analysis are all done through the use of computers, which have become as integral to the mass spectrometer as any of its other components.

There are no limits to the types of matter that can be studied with MS. MS was originally used to determine the existence of the stable isotopes of the elements in the periodic table.[1] [The word *isotope* was suggested by Frederick Soddy (1877–1956) as a student and collaborator of Ernest Rutherford at McGill University in Montreal, Canada, in 1913. Isotopes are different forms of the same element that have the same atomic number, but differ in their relative atomic mass due to a difference in the number of neutrons present in the nucleus of the atom. The word is derived from the Greek words *isos* (equal) and *topos* (places), 'having the same place' in the periodic table.] MS has been used as a preparative technique [e.g. the separation of ^{235}U from uranium[2]]. It is also used for the identification and quantitation of various organic substances from the simplest gases such as methane and halomethanes to complex biomolecules such as proteins, oligonucleotides, and noncovalent complexes. Today, MS plays an important role not only in organic and biochemistry but also in inorganic chemistry such as the determination of metal contaminants in silicone wafers, drinking water, soils, industrial waste, etc. Mass spectrometers are not only found in analytical laboratories but also inside the helmets of space suits (to determine the level of gases that may pose a hazard), in tanks and other battlefield vehicles and on ships and aircraft (to detect the presence of chemical and biological warfare agents), and as more conventional field-portable instrumentation (for use at crime scenes, hazardous

Figure 1 The concept of MS is to form ions from a sample, separate the ions based on their mass-to-charge ratio (this can be considered to be the same as the mass because the ion has only a single charge in most cases), and measure the abundance of the ions. In modern MS instrumentation used in environmental analyses, all of the functions (ionization separation of the ions, rate of data acquisition, detection of the ions, and storage of the data) are under computer control. Gaseous molecules are ionized in the ion source to form molecular ions. Some of the resulting molecular ions will fragment. The molecular and fragment ions are accelerated into a mass analyzer (mass analyzer and mass filter are used interchangeably). By various processes, ions of differing m/z values pass through the mass analyzer one at a time to reach the detector. When the ions strike the detector, they are converted into an electrical signal which, in turn, is converted into a digital response that can be stored by the computer. (Reproduced by permission from O.D. Sparkman, 'Mass Spectrometry', in *Encyclopedia of Environmental Analysis and Remediation*, ed. R.A. Meyers, Wiley, New York, 1998.)

material spills, industrial waste sites, chemical-plant production locations, etc.). MS is used to characterize and analyze surfaces such as metallic and nonmetallic skins on the wings of modern aircraft or the coatings on papers specially prepared for use with laser printers.

Two factors make MS one of the most powerful analytical chemistry techniques in use today. The first is the simplicity of MS. The analytes are characterized by "... the mass of their molecules and the masses of the pieces of their molecules".[3] Unlike the spectroscopic techniques that rely on the absorption of specific energies of electromagnetic radiation, there is no knowledge of esoteric characteristic wavelengths of absorption or resonance frequency of atoms required to deal with resultant data. The second factor is that MS yields more information about the composition and structure of a molecule from less sample than any other analytical technique. MS is different from the other various spectrometries in that it deals with analytes one molecule at a time rather than the behavior of the total sample. The only negative aspect of MS is that the sample is consumed by the analysis [with the exception of Fourier transform mass spectrometry (FTMS)]; however, the sample size required is small enough to make this particular disadvantage insignificant. MS has been used to determine the mass of a complete protein from attomole quantities[4] and to quantitate unambiguously identified subpicogram amounts of the pesticide malathion on orange peel.[5] It is used to determine the age of artifacts [isotope-ratio mass spectrometry (IR MS)], contamination of the surface of metal and composite airplane wings [secondary ion mass spectrometry (SIMS)], and the components that give fresh-baked bread its delightful aroma. The list of applications is endless.

Another important distinguishing characteristic of MS is that it deals with the mass of the isotopes of the individual elements rather than the atomic weight of the elements. See Note 1 at the end of the article.

The field of MS was originally referred to as *mass spectroscopy* by Sir Francis William Aston in 1920 (English Nobel Laureate in Chemistry, 1922; 1877–1945; one of the founding fathers of MS),[6] who called his instrument a *mass spectrograph* because it had an arrangement of the electric and magnetic fields, used to separate the ions, that was analogous to that of an achromatic set of prisms without lenses, which produced a spectrum of lines such as an optical spectrograph. *Mass spectroscopy* became the all-encompassing term for the use of mass spectrographs (instruments that focused ions on to a plane for detection on a photographic plate or an array detector) and mass spectrometers (instruments that focus ions to a point for electrical detection one m/z value at a time) as well as the studies of isotopic abundances, precise mass determination, analytical chemical use, appearance potential, etc. However, the term *mass spectroscopy* is too broad and is no longer recommended. The preferred term for techniques involved with the measurement of ions according to their m/z values and their abundances is *MS*.

Over the last half-century, the field of MS has been extensively reviewed. Other than from an historical perspective, only the more recent general references are of value.[7–9] This article reviews MS from an historical perspective as opposed to the technology of the instrumentation and the utility of the applications.

The field of MS is discussed in terms of ion-separation methods, ionization techniques, or applications. All of these are extensively covered either in this section of the Encyclopedia or in one of the Applications sections. An important aspect of the successful use of an analytical technique is a clear understanding of the method by which the data are acquired. It is therefore worthy of mention as to sources of extensive and definitive information on m/z analyzers [magnetic-sector,[10] transmission-quadrupole (TQ),[11] quadrupole ion-trap (QIT),[12] time-of-flight (TOF),[13] and Fourier transform ion cyclotron resonance (FTICR)[14]]. These references provide a seminal understanding of the

physics of ion-separating techniques employed by these individual analyzers.

The literature sources for the understanding of ionization techniques are somewhat less specific. The important aspect of electron ionization (EI), which is the technique most often used with gas chromatography/mass spectrometry (GC/MS), is understanding the fragmentation mechanisms that result in the mass spectra. This understanding is achievable through a series of excellent references[15] or courses available from the American Chemical Society (ACS)[16] or the American Society for Mass Spectrometry (ASMS).[17] An important aspect of chemical ionization (CI), which is the technique most often used to obtain molecular weight information of a compound whose EI mass spectrum does not exhibit a molecular ion peak or that has some degree of volatility but is best separated by liquid chromatography/mass spectrometry (LC/MS), is the choice of the appropriate ionization compound[18] (reagent). In order to obtain EI and CI spectra of some compounds, it may be necessary to form volatile derivatives.[19]

The desorption/ionization (DI) technique of electrospray (ES) is still evolving. There are numerous descriptions of the mechanism involved in getting ions from the solution into the gas phase.[20] The other current popular DI technique, matrix-assisted laser desorption/ionization (MALDI), requires less of an understanding of the ionization mechanisms but more of an appreciation for the sample preparation[21] (the matrix). Other DI techniques such as fast atom bombardment (FAB), field desorption (FD), SIMS, and desorption chemical ionization (DCI) will be reviewed in this article and/or other articles in the Encyclopedia.

At this time, there is not a good single reference for the general technique of LC/MS; however, because of its maturity, GC/MS methods and techniques have been well elaborated.[22] MS receives extensive coverage in both the fundamentals review and the applications review

Figure 2 A partial time line of the history of MS. (Adapted with permission from Siuzdak.[23])

issues, which appear in alternating years, of *Analytical Chemistry*.

2 HISTORY

The history of MS is graphically chronicled in Figure 2, which is an adaptation from Gary Siuzdak's History of MS page.[23] Siuzdak's Web site also contains literature references for many of these events.

MS had its embryogenesis with the report of the German physicist Eugene Goldstein (1850–1930) at the Berlin Observatory that luminous rays in a discharge tube containing gases at low pressure emerged in straight lines from holes in a perforated metal disk used as a cathode. He called the rays Kanalstrahlen (canal rays).[24] This report has been referred to as the first MS paper[10] although the terms *mass spectrum* and *mass spectrograph* were suggested by Aston ca. 1920,[6] and *mass spectrometer* was a term first used by two well-known early pioneers of MS, William R. Smythe (US scientist) and Josef Heinvich Elizabeth Mattauch (Austrian physicist), ca. 1926.[6]

In 1895, the suggestion of the French physicist Jean Baptiste Perrin (1870–1942) that these rays were associated with a positive charge was confirmed by the German physicist and 1911 Nobel Laureate Wilhelm Wien (1862–1928).[25,26] Wien showed that these rays were deflected in a magnetic field and that their behavior could be studied by the combined effects of magnetic and electric fields.

The first instrumentation for the measurement of masses of charged particles was described in a lecture by Sir Joseph John Thomson entitled 'Cathode Rays' on April 30, 1887, at the Friday Evening Discourses in Physical Science held at the Royal Institution in London[27–29] (Figure 3a and b). This particular event was Thomson's announcement of the discovery of the electron for which he was awarded the 1906 Nobel Prize in Physics. Thomson called the Kanalstrahlen rays *rays of positive electricity*. Thomson became aware of the potential for these as tools in the analysis of matter and published the first MS book: *Rays of Positive Electricity and Their Application to Chemical Analyses*.[30] Thomson's discovery and initial instrument were followed by the development of a sector-based (magnetic and electric) mass spectrograph ca. 1911, which resulted in Francis William Aston (one of Thomson's collaborators at the Cavendish Laboratory) being awarded the 1922 Nobel Prize in Chemistry (Figure 4). This instrument employed velocity focusing. Aston's 1920 paper, 'The Constitution of Atmospheric Neon',[31] is considered the first paper in applied MS.[21]

Figure 3 (a) Photograph of the positive-ray apparatus used by Thomson.[30a] (b) A schematic representation of the parabola mass spectrograph built by Thomson that includes: A, the gas inlet; B, the anode; C, the discharge tube; D, the port to the vacuum system; E, the cathode; F, the magnetic shields; G, the water jacket for cooling; H, the insulators; and J, the photographic plate used to detect the ions.[6]

Figure 4 A schematic representation of Aston's velocity-focusing mass spectrograph.[45]

During the same period that Aston was pursuing the mass spectrograph, the Canadian–American physicist Arthur Jeffery Dempster (1886–1950), in an independent effort, developed a single magnetic-sector instrument that employed direction focusing of constant energy

Figure 5 An illustration of Dempster's direction-focusing mass spectrometer that includes E, the ion-detection device; G, the glass ion-source housing containing the filament F that was heated to produce electrons that bombarded the platinum sample holder P; and B, the analyzer section surrounded by the magnet. A potential difference between the sample holder and the first slit (S_1) provided the ion acceleration.[6]

ions at the University of Chicago. Whereas Aston's instrument provided accurate m/z values, Dempster's instrument provided accurate ion abundances (Figure 5). This distinction between velocity focusing and direction focusing was the difference between mass spectrographs and mass spectrometers, respectively.

In the decade that followed (1911–1925), MS developed as a distinct field mainly as a result of these three pioneers. In the late 1920s, Dempster proposed the combination of direction focusing and velocity focusing with W. Bartky.[32] The first double-focusing mass spectrometers began to appear ca. 1934 with the Dempster, Mattauch–Herzog, and Bainbridge–Jordan geometries (the word "geometry" in MS refers to the arrangement of the electric and magnetic sectors between the ion source and detector in the mass spectrometer) (see section 2.6.1).

In these formative years, MS was used to determine the isotopes of the elements, to study atomic theory and thermodynamics, and to determine metabolic pathways through the analysis of biological substances generated with stable isotope-labeled precursors. The only other books published on MS were by Aston.[1,33] Although these books (two editions each) describe advances that had appeared in the literature, they concentrated on the primary use of MS as a tool for the determination of the mass of the isotopes of the elements. It was Aston's determination that there was more than one stable isotope of oxygen that led to the difference in the physical and chemical definitions of the atomic mass unit (amu). Prior to this time, there had been a single definition of the atomic mass unit, which was that 1 amu was equal to 1/16 the atomic weight of oxygen. Aston defined the amu as 1/16 the mass of the most abundant naturally occurring stable isotope of oxygen, ^{16}O. This definition resulted in a factor of 1.000275 difference between the standards, which was resolved by the replacement of the amu with the unified atomic mass unit (u or, in current terms, Da, the dalton) in 1962. Although unsubstantiated, it has been reported that Aston once said, 'Once all the isotopes of the elements in the periodic table had been determined, there would no longer be a need for MS'.

As the users of these early mass spectrometers (always custom built) began to complain about the presence of ions that did not correspond to their analytes, the organic chemists realized this was coming from organic impurities in the samples. This led to a growing interest on the part of the organic chemist. Commercial instruments began to appear, and MS became an essential tool in the petroleum industry. The 1940s saw the birth of organic MS. Not all organic compounds were suitable for mass spectral analysis. Since ions were separated in the gas phase, they had to be formed in the gas phase in this early instrumentation. This meant that the analyte had to be volatile and nonthermally labile.

While the development of the atomic bomb by the United States was underway, many of the developments in MS became shrouded in secrecy owing to the key role that it played in this development and the actual implementation of the bomb (Figure 6a and b).[2]

In the 1950s, a great deal of research took place on MS instrumentation. This led to several different ways of separating the ions according to their m/z values. Although the sector-based instruments (mass spectrometers are usually described by the way which ions are separated according to their m/z values) dominated the analytical chemistry laboratories, the desire for lower cost, simpler to use instruments led to the discovery and development of the TOF mass spectrometer, followed by the TQ, the ion cyclotron resonance (ICR), and eventually the QIT mass spectrometer. The pioneering efforts of this period led to the instruments of predominant use today. This same era was the beginning of the commercial MS industry with manufacturers appearing in the UK, Germany, and Japan to join those already established in the USA.

The gas chromatograph (GC), developed ca. 1952 by A. James and A. Martin,[34] was interfaced to the mass spectrometer in the mid-1960s.[35,36] This development allowed mixtures of organic analytes to be separated into relatively contaminant-free individual compounds that were delivered to the mass spectrometer in the gas phase.

(a)

(b)

Figure 6 (a) An illustration of the Calutron's second-stage β units used at Oak Ridge National Laboratory to produce weapons-grade ^{235}U from the first stage. The origin of the name for this preparative instrument is 'CalU' from the University of California, Berkeley, and the Greek suffix 'tron', which means instrument – Calutron. ORNL Drawing 42951.[2] (b) Photograph of two workers cleaning one of the Calutron's vacuum system tank liners at the Y-12 Electromagnetic Separation Plant, previously known as the Clinton Engineering Works.[2]

GC/MS was limited in its usefulness by the plethora of data produced until the development of the minicomputer later in that same decade. The 1960s were also the period that MS of organic compounds began to be explained by organic reaction mechanisms, which allowed for a more detailed interpretation of the mass spectral data resulting from the EI of an organic compound and the prediction of fragment ions based on the presence of elements and substructures. New ionization techniques such as chemical and field ionization (FI) were also developed in the 1960s to be able to directly determine the molecular weight of compounds whose EI mass spectra did not have a molecular ion peak.

The gas chromatograph–mass spectrometer (GC-MS) became one of the most widely used analytical instruments by organic chemists in the 1970s,[37] and thus began the eventual dominance of the TQ mass spectrometer over the sector-based instrument that had ruled for the first 40 years of MS. With its lower price, more rapid spectral-acquisition ability, and ease of use compared with the sector-based instruments, the TQ mass spectrometer was ideally suited for GC/MS. In the late 1960s and early 1970s, new computer techniques were developed that resulted in easier methods of dealing with the GC/MS data.[38] The triple-quadrupole m/z analyzer was developed to determine additional structural information on the fragment ions produced by EI and CI.[39] The role of positive ions had dominated the MS of organic compounds; however, in the 1970s, the discovery of the formation of negative ions under CI conditions led to new levels of sensitivity in GC/MS.[40]

The high-performance liquid chromatograph (HPLC)[41] was interfaced to the mass spectrometer in the 1970s. This marriage was not as successful as that of the GC and the mass spectrometer. Owing to the volatile nonthermally labile requirement of the analyte (even though the analyte could be separated from the mobile phase of the HPLC), ionization was not always possible. The liquid chromatograph–mass spectrometer (LC-MS) remained a laboratory curiosity until the development of DI techniques. At the end of the 20th century, the LC-MS had become an even more prevalent instrument than the GC-MS. Part of the reason for this emerging dominance is the ability to form ions of analytes in the liquid chromatograph (LC) eluates using the atmospheric pressure ionization (API) technique of ES. The technique of LC/MS has also been popularized through the other API technique of atmospheric pressure chemical ionization (APCI). Unlike ES, APCI forms the ions in the gas phase. Although the ions must still be in the gas phase for their separation according to mass-to-charge ratio to take place, analytes that may not survive the rigorous temperature conditions of the GC required for their separation can pass through the LC process without harm and still have ions that end up in the gas phase. The API LC/MS techniques do not provide the same level of structural information as can be obtained from the gas-phase EI process; however, structural information can be obtained through techniques of mass spectrometry/mass spectrometry (MS/MS) and using in-source collisionally activated dissociation (CAD), which are also fairly recent developments.

The late 1980s and the 1990s constitute the period during which the DI technique of MALDI developed and became a routine tool. ES is also referred to as a DI technique. These two DI techniques allow for transfer of ions formed in solution (ES) or in a solid (MALDI) to the gas phase for m/z analysis. The DI techniques have eliminated the volatile nonthermally labile requirements for analytes allowing for the characterization of synthetic organic polymers and biopolymers by MS. In this same time period, inductively coupled plasma (ICP) ionization for inorganic substances in solution was linked with MS. In addition, other DI techniques such as SIMS has become a routine tool in the analysis of both organic and inorganic substances on the surfaces of substances important to the material scientist. These last two techniques have given MS a rebirth in the field of inorganic analyses.

Since the determination of stable isotopes of the elements of the periodic table by MS, the widest impact of the analytical technique has been in organic chemistry. MS still plays an important role in inorganic chemistry and geochemistry, but the major discoveries and uses are in the organic field.

2.1 Beginning to the 1940s

At the time Thomson reported his parabolic instrument using electrical and magnetic fields, he referred to the particles that are known as *electrons* as *corpuscles* (small negatively charged particles from which atoms were built up). This made Thomson the first mass spectrometrist to generate neologisms (unfortunately, a trait not uncommon to modern mass spectrometrists) that later fell into disuse (*rays of positive electricity* and *corpuscles*). With the collaboration of Aston, Thomson's apparatus was improved to the extent that these *rays of positive electricity* (ions of positive charge) could be separated according to their mass-to-charge ratios. Their joint efforts led to the 1910 improvements of the Thomson positive-ray tube, which was used in the 1912 discovery of the two stable isotopes of neon. This report was the first of nonradioactive isotopes[31] and had a profound effect on the development of atomic and nuclear theory.

After World War I, Aston returned to the Cavendish Laboratory, continued to collaborate with Thomson, and dedicated his career to the separation of the two isotopes of neon and the proof of their existence beyond doubt. This work produced continued improvements of Thomson's apparatus and culminated in the development of the mass spectrograph. Thomson is the discoverer of MS, and Aston is the developer of the mass spectrometer.

In the early part of the 20th century, the technique of positive-ray analysis took two different paths: (1) that pursued by Aston, which was the accurate determination of mass; and (2) that pursued by Dempster (in the USA), which was more suited for the determination of the abundance of the ions. Aston's instrument results in the ions striking a photographic plate that is on a focal plane. Aston called this a mass spectrograph and also coined the term *mass spectrum*. The Dempster instrument focused the ions of one m/z value at a time on a point so that they could be converted to an electrical signal that is then amplified and measured. Through the ability to record accurate ion abundances, Dempster was able to show that seven out of every 1000 uranium atoms were the isotope with a nominal mass of 235. Thomson, Aston, and Dempster (Figure 7a–c) are considered to be the founding fathers of MS.[10]

Aston foretold the impact of MS on atomic theory in his 1922 Nobel address where he forecast both nuclear bombs and power plants based on the future use of the energy in an atom's nucleus.

Building on the developments of the founding fathers of MS, others began to advance the field in the period just prior to World War II. During this period, Dempster developed EI. [EI was originally called electron impact. This is a process by which gas-phase molecules at a pressure of $>10^{-3}$ Torr are ionized by a beam of electrons, produced by a hot wire (filament), that have been accelerated by 70 V (i.e. 70 eV).] EI is used in modern mass spectrometers where analytes are in the gas phase. There has been more study of EI processes and fragmentation than all others types of mass spectral ionization techniques combined. All of the large archives of mass spectral data contain EI spectra obtained at 70 eV. Dempster also developed the spark-source and vacuum-vibrator techniques used in the analysis of inorganics in solids.

During this pre-World War II period and after the significant developments of the Aston/Thomson/Dempster era, most of the advances in MS were made in physics. A series of seminal articles were presented by Roboz (p. 491).[10] These papers began to appear in the early 1920s and continued through the mid-1930s. After that time, there were few references, if any, to MS because of its strategic importance to the war effort both in the area of organic chemistry and nebular weapon development.

One important aspect of the use of MS came about through the isolation of heavy water and the discovery of deuterium by Harold Clayton Urey (1893–1981), a US chemist at Columbia University, New York, in 1934. This accomplishment resulted in Urey's receipt of the Nobel Prize for Chemistry in 1934. David Rittenberg, one of the doctoral students in Urey's laboratory at the time of this discovery, studied some of the thermodynamic properties of compounds containing these newly discovered isotopes. Shortly after receiving his PhD in 1934, Rittenburg joined the Biochemistry Department at Columbia University, where he remained until his

death in 1970. He and a departmental colleague, Rudolf Schoenheimer, began a study in 1935 of intermediate metabolism using stable isotopes. They were the first to use deuterium labeling to investigate the metabolism of amino and fatty acids. This original work of Rittenburg and Schoenheimer resulted in the 'dynamic state of body constituents' concept, which said that the apparent static state of many constituents results from rapid opposing reactions at nearly equal rates.[42] Over the next 36 years, Rittenburg published over 200 papers. Many of the specifics of using stable isotope-labeled compounds in the determination of metabolic pathways is presented by Richard Caprioli,[43] the last person to receive a PhD under the direction of Rittenburg.

The ability to use the difference in mass between an analyte and its analog labeled with a stable isotope of nitrogen, carbon, oxygen, and/or hydrogen has resulted in one of the primary uses of MS in the biological sciences. The labeled material can be used to determine which compounds resulted from the metabolism of an ingested drug or nutrient. Labeled analogs can be used as internal standards, which result in lower detection limits owing to finite analyte-absorptive properties of a particular analysis. As internal standards, labeled analogs of an analyte will behave chemically and physically the same as the analyte. This means reduced errors in quantitation due to internal standard effects. The most difficult step in the use of stable labeled isotopes is the preparation of the label compound. These selectively labeled compounds have been extensively used to determine the mechanisms of fragmentation. One of the pioneers in this area was the Swedish medical scientist Einar Stenhagen (1911–1973), who received several patents on the synthesis of labeled compounds of biological interest. He was also granted a patent for the jet separator, the most popular device for the interface of high-flow packed columns and large-bore, capillary GC columns [530–750 μm inner diameter (ID)], which have high optimum flow rates (15–30 mL min^{-1}) to a mass spectrometer.[44]

In spite of the extensive contributions by Rittenburg based on the use of MS, he only receives token mention[10,45,46] in some of the early references on MS and none in others.[6,47] This lack of reference is one of the reasons for the importance of the two early books edited by George Waller at Oklahoma State University.[43,44]

It was not until the 1940s that commercial instruments began to appear. All the instruments used in isotope-labeling studies were built as one-of-a-kind research curiosities by their user or colleagues of these users. The first of these commercial instruments was the Consolidated Engineering Corporation's (Pasadena, CA) CEC 21-101. Until that time, mass spectrometers were custom built by researchers such as Dempster. Among this group of early innovators of the instrumentation were Dempster, Smythe, Mattauch (in cooperation with Richard Herzog in Germany ca. 1934–1936), and the American physicist Alfred Otto Carl Nier (1911–1994), who was a key figure in the Manhattan project. One of the two most popular geometries for a double-focusing instrument was a result of this era, the Mattauch–Herzog mass spectrograph, with ion optics worked out by Herzog[48] and built by Mattauch in Germany.[49] The other is the Neir–Johnson geometry developed by Neir and Edger G. Johnson, a master's degree graduate student, after World War II, ca. 1948.[50]

One of the hindrances to the development of MS was the crude state of knowledge about the production of a vacuum. The low-pressure requirement of MS was such that poor vacuum technology resulted in hours of frustration. One very significant improvement that came out of the war research into MS was advances in vacuum systems.

The Consolidated Engineering company was the first commercial manufacturer of mass spectrometers. This pioneer mass spectrometer manufacturer was founded by Herbert Hoover, Jr, in 1937 as the engineering and manufacturing subsidiary of the United Geophysical Company to develop a mass spectrometer to locate oil deposits by detecting hydrocarbon gases emitting from the ground. The company had close connections with the California Institute of Technology and the petroleum industry. The initial project was a failure due to the ubiquitous nature of methane in ground-seepage gas. However, the instrument was useful as a replacement for a distillation analysis used to detect light-end hydrocarbon gas mixtures in the production of aviation fuel.[51] The company was later renamed the Consolidated Electrodynamic Corporation because of restrictions of the use of the words 'engineering' and 'engineer' in the state of Texas to those that were licensed by the state as engineers. The company was then sold to Bell & Howell and later to DuPont. While under the control of DuPont, the manufacture and support of mass spectrometers was terminated.

The CEC 21-101 had an m/z range of 16–72, and it was able to produce a spectrum over this range of a mixture of C_1–C_5 hydrocarbons in 20 min. This initial design was refined into several subsequent models culminating in the CEC 104, which had a unit-resolving power over its entire m/z range to 700. The last of these instruments was manufactured in 1965. The last instrument was taken out of service by Exxon in 1997.

One of the hindrances to the advancement of MS after the introduction of the CEC 21-101 was a requirement in the CEC sales agreement demanding that all data made available be made available to CEC.[52] This requirement was not well received in the competitive petroleum industry and led to an all-glass instrument

that was produced by Westinghouse Electric Corporation (the Type LV, a 90° sector instrument as opposed to the CEC 180° instrument) in collaboration with Humble Oil and Refining and several other oil companies. These Westinghouse instruments were some of the first used outside of the temples of MS (University of Minnesota, Princeton, Harvard, University of Chicago, and Cal Tech) for the study of organic compounds. After the end of the war, CEC changed its information-sharing policy and went on to dominate the field of commercial MS through the 1960s. The end of the 1940s saw the beginning of the second era of MS.

It is interesting to note that the CEC 21-101 mass spectrometer was copied from Nier's 1937 instrument, which had an analyzer copied from Dempster's 1918 instrument. Nier built this instrument while studying with Kenneth T. Bainbridge at Harvard University. Unlike Dempster's 180° instrument, the Nier mass spectrometer had an ion source with both electric and magnetic fields. This instrument represented the birth of commercialization of academic research in MS.

2.2 The Birth of Organic Mass Spectrometry

Until World War II, MS had only a small role in organic chemistry. At the end of the war, advancements in MS had been largely confined to improvements in instruments to separate isotopes of elements and how to make these instruments suitable for the preparation of production quantities of isotopes that played a major role in atomic weapons production. There were only three books devoted to the subject of MS – one authored by Thomson[30] and two by Aston.[1,33] All three of these books had two editions. The first book to appear after World War II was G.P. Barnard's *Modern Mass Spectrometry* in 1953.[45] This book was similar to those of Aston and Thomson in that it concentrated on the instrumentation and ion behavior. Treatment of applications was somewhat broader than that of Thomson or Aston, but still only of footnote quality and quantity. And keeping with that philosophy, there is only a brief mention of Rittenburg's use of MS.

Although MS continued to be primarily the privy study of the physicist, the role of the organic chemist began to emerge with a high degree of visibility. Several companies (CEC in the USA, AEI in the UK, Atlas in Germany, and Hitachi and JEOL in Japan) began the development of commercial instruments after World War II primarily for use in the analysis of organic compounds. This proliferation of manufacturers led to more users and a desire for people to discuss common experiences and problems. According to Seymour Meyerson, the first MS meeting, the symposium on mass, infrared (IR), and ultraviolet (UV) spectrometry,[53] was held in the USA and organized by Rubber Reserve Company and the Petroleum Administration for War. The first review of mass literature appeared in *Analytical Chemistry* in January 1949.[54] In this review, John Hipple of the National Bureau of Standards (NBS), Washington, DC, a Division of the United States Department of Commerce,[55] pointed out that in *Chemical Abstracts* there had been 11 references to MS in 1943, 15 in 1944, 17 in 1945, 26 in 1946, and 40 in 1947. Hipple's review had 165 citations as compared with that of Alma Burlingame in the same type of review published in 1998,[9] which had 1551 citations divided into nine categories: Overview (5), Scope (173), Innovative Techniques and Instrumentation (364), IR MS (89), High-power Lasers in MS (51), Dissociation by Low-intensity IR Radiation (18), Polymers (61), Peptides and Proteins (264), and Oligonucleotides and Nucleic Acids (166).

September 6–8, 1951, were the dates for a symposium on MS in physics research, held in Washington, DC, as one of 12 symposia commemorating the semicentennial of the then NBS [now the National Institute of Standards and Technology (NIST)]. John Hipple organized this symposium in cooperation with the Office of Naval Research.[56] Of the 36 presentations, only one pertained to the use of MS in organic chemistry: 'Mass Spectra of Heavy Hydrocarbons', by M.J. O'Neal, Shell Oil Company (Houston, TX). This presentation included spectra of aliphatic hydrocarbons and aliphatic hydrocarbons with aromatic substitutions. The remainder of the presentations revolved around instrumentation and ion physics.

Similar conferences were organized in the UK by the MS Panel of the Institute of Petroleum in 1950 and 1953. The proceedings of the second of these meetings, held October 29–31, 1953, at the Institute of Electrical Engineering in London with 200 people in attendance, were published.[57] This conference consisted of five half-day sessions, with a total of 26 presentations. A commercial exhibition associated with the conference had four companies displaying computing equipment: British Tabulating Co., Ltd., Elliot Bros. (London), Ltd., Ferranti, Ltd., and International Business Machines (United Kingdom), Ltd., and two companies displaying mass spectrometers, Metropolitan–Vickers Electrical Company, Ltd., and Vacuum Industries Applications, Ltd. This conference, as could be guessed by the name of the organizer, was much more related to the use of MS in organic analyses.

The proliferation of mass spectrometer manufacturers led to the organization of 'user meetings' where people using the same types of instruments could gather and discuss common problems and tell of their new discoveries. One such user meeting organized jointly by CEC and General Electric Corporation at the 1952

meeting (third meeting) of the Pittsburgh Conference on Analytical Chemistry and Applied Spectroscopy (Pittsburgh, PA), sponsored by The Society for Analytical Chemists of Pittsburgh and The Spectroscopy Society of Pittsburgh, became the E-14 Committee (an educational committee) of the American Society for Testing and Materials (ASTM). Proceedings of the annual E-14 meeting have been published since 1961. At the 1969 E-14 Committee meeting in Dallas, TX, the membership formed the ASMS, which is the largest organized group of mass spectrometrists in the world today. After 1969, the published proceedings were under the ASMS name. See Note 2 at the end of the article.

As an outgrowth of the two meetings organized by the MS Committee of the Institute of Petroleum in the UK, an international MS meeting, the International MS Conference, began in 1958. There have been 14 of these triennial meetings. The first six meetings were held in the UK. Beginning with the seventh meeting (Florence, Italy), each succeeding meeting has been held in a different European country. The 15th International MS Conference is scheduled for Barcelona, Spain, in 2000.

The instrument manufacturers' user meetings are still significant, and there were at least 10 companies holding these meetings at the 1999 annual ASMS Conference on MS and Allied Topics.

In the early 1960s, John Beynon in the UK (1960) followed by Klaus Biemann in the USA (1962) published two of the classical books on MS of organic compounds: *MS and its Applications to Organic Chemistry*[46] and *MS: Organic Chemical Applications*.[47] These books were quickly followed by a series of books showing that mass spectral data could be related to mechanisms of organic reactions.[58] In addition to these important works pertaining to organic MS came another series of general-interest books from both American and British authors. Two of the most important were those authored in the US by Robert W. Kiser (Kansas State University, Lawrence, KS)[6] and John Roboz (Air Reduction Company, Inc., Murray Hill, NJ).[10] A book edited by George Waller (Oklahoma State University) was published in 1972,[59] *Biochemical Applications of Mass Spectrometry*. This book is the first book devoted to MS and biochemistry.

Through cooperation between those interested in MS for applications in organic chemistry and biochemistry such as Biemann and Beynon and the several instrument companies that were vying for the market, a number of improvements were made in the magnetic-sector mass spectrometer. These improvements included more rapid acquisition rates and the development of mass accuracy measurements that allowed the assignment of empirical formula to ions whose mass was determined to the nearest 10 millimass units. During these early phases of organic MS, the instruments were used as separation devices for mixtures such as the paraffin, olefin, naphtha, and aromatic (PONA) analyses used by the petroleum industry, in the determination of isotopically labeled compounds purified from complex biological mixtures, and in the determination of the structure of purified compounds.

The period after World War II also saw developments in nonmagnetic-field technologies to separate the ions. These developments resulted in the TOF, TQ, and QIT mass spectrometers. Details of these developments can be found in section 2.6.

2.3 Gas Chromatography/Mass Spectrometry – A Tremendous Success

Almost from the appearance of the first paper on gas chromatography, the organic mass spectrometrist saw the potential advantage of separating a complex mixture into nearly pure components followed by mass and structural analysis with no need for human intervention. Although the technique of GC/MS had the greatest potential for those in the biological science, the first published report of this interface that involved dilute analytes in an above-atmospheric-pressure gas being introduced into an instrument that operates at pressures as low as 10^{-10} Torr [pressures in high vacuum are referred to in Torr by most manufacturers of mass spectrometers. 1 Torr is equivalent to 1 mm of mercury or pascal (Pa); 1 Torr = 133.322 Pa; 1 Pa $\approx$ 0.0075 Torr; 1 atm = 760 Torr or 1.013×10^5 Pa (exactly, by definition)] came from the bulk chemical industry – Dow Chemical in Midland, MI.[35,36] This first effort used a TOF mass spectrometer because of its rapid spectral acquisition rate compared with a sector-based instrument and an oscilloscope fitted with a Polaroid camera to record the spectra. Less than 1% of the GC eluate was put into the mass spectrometer.

Three major hurdles had to be overcome in order for GC/MS to be an executable analytical technique: (1) the problem with the amount of gas expelled from the GC and the requirement for high vacuum in the mass spectrometer; (2) the need for rapid mass spectral acquisition to compensate for the ever-changing partial pressure of the analyte; and (3) the tremendous amount of data collected during a single GC/MS analysis.

Dealing with the pressure difference and the low analyte concentration in the GC eluate was undertaken by a number of different investigators. This work resulted in several different devices that are known as GC/MS separators. The most popular was the jet separator invented, and later patented, by Einar Stenhagen (Swedish medical scientist) and perfected by Ragnar Ryhage.[60] In addition, Jack Watson, while a PhD student of Klaus Biemann at Massachusetts Institute of Technology (Cambridge, MA), and Duane Littlejohn and Peter Llewellyn, at the

Figure 8 A graphic illustration of a two-stage jet separator. (Reproduced by permission from O.D. Sparkman, 'Mass Spectrometry', in *Encyclopedia of Environmental Analysis and Remediation*, ed. R.A. Meyers, Wiley, New York, 1998.)

Varian Research Center in Palo Alto, CA, also developed separators.[61,62] The Llewellyn separator enjoyed some commercial success but not to the same extent as that of the jet separator (Figure 8). As the use of capillary columns (50–250 μm ID GC columns and flow rates of 1–2 mL min^{-1} where the stationary phase is coated on the inner walls) replaced the packed columns of the 1960s and 1970s (2–5 mm ID GC columns and flow rates of 20–30 mL min^{-1} where the stationary phase is a high-boiling liquid coated on diatomaceous earth particles packed inside of the column), the need for these devices used to enrich the concentration of the analyte in the GC eluate passing into the mass spectrometer as well as reducing the total volume of gas introduced to the mass spectrometer was no longer needed. Jet separators are still used with larger diameter capillary columns (530–750 μm ID), but the use of these columns is becoming less as new preconcentration techniques are developed.

Although the use of the TOF mass spectrometer appeared to resolve the problem of rapid data acquisition, there were other problems associated with this type of m/z analyzer that kept it from becoming a part of a successful commercial GC-MS. With the potential for GC/MS, the first efforts were put into interfacing existing instruments to the GC. None of these endeavors were very successful. As more investigation took place, it was found that GC/MS was as different from either gas chromatography or MS as these two techniques were from one another. The first commercial instrument built as a GC-MS was the LKB 9000 produced in Sweden by LKB Instruments in the mid-1960s. Other manufacturers produced a mass spectrometer with a GC inlet, but the LKB 9000 was neither a GC with a mass spectrometer as the detector nor a mass spectrometer with a GC inlet. LKB pioneered the technology required to remove the carrier gas from the GC eluate from packed columns (enriching the flow with analyte prior to introduction into the mass spectrometer: jet separator). The LKB 9000 was a single-focusing magnetic-sector instrument. To optimize it for GC/MS, special considerations were given to the vacuum system and the scanning of the magnetic field. In addition,

Figure 9 An illustration of mass spectral data acquired with a three-channel light-beam oscillographic recorder.

emphasis was put on the detector system to allow for the rapid acquisition of data required for GC/MS analyses. The first prototype LKB 9000 was delivered to George Waller at Oklahoma State University (Stillwater, OK) in 1964. The LKB 9000 did not address the issue of the amount of data that is acquired in a GC/MS analysis. This instrument used a light-beam oscillographic recorder to record the mass spectra. Spectra were manually selected for recording (Figure 9).

With the development of the minicomputer in the mid-1960s, it became possible to deal with the vast amount of data generated in a single GC/MS analysis. Before that time, acquiring spectra over a range of 200–250 m/z units every 2–3 s in a GC analysis that lasted for 15–30 min produced as many as 225 000 data points (mass spectral peaks in multiple spectra) that had to be dealt with manually. Data were typically acquired by using a multichannel analog recorder that increased the amount of data and the complexity in converting it to usable information. The paper used to record these data was usually light-sensitive and had a short life before the recorded images would fade into oblivion especially if exposed to fluorescent or sun light. This volume-of-data problem greatly reduced the number of samples that could be analyzed with a reasonable amount of effort. The minicomputer allowed for the automated collection of data. The generation of several different types of chromatograms was made possible by computer processing the m/z and intensity data recorded by the data system (DS). Sums of intensities for all the m/z values in each spectrum (total ion current) could be plotted versus the spectrum numbers to produce a reconstructed total ion current chromatogram. Intensities of specific m/z values, sums of m/zvalues, or ranges of m/z values could be plotted versus spectrum numbers to produce

reconstructed 'mass chromatograms'. A DS typically could display bar-graph mass spectra (unit resolution and intensity data) for the data from individually acquired spectra. These bar-graph spectra would generally be normalized to the most intense peak (base peak) and could have peaks due to ions from substances other than the analyte (background) deleted. Even with these primitive abilities (by today's standards), the number of samples that could be handled in a week increased by orders of magnitude.

GC/MS began to become a routine technology with the introduction of the TQ GC/MS instrument. The first commercial TQ GC/MS system was developed by Finnigan Corporation (San Jose, CA), now part of ThermoQuest. According to Bob Finnigan, one of the founders of Finnigan Corporation, in an *Analytical Chemistry* A-pages article,[37] the first Finnigan 1015 GC/MS instrument (prototype) was delivered to Bert Halpern and Walt Reynolds at the Stanford Medical School Department of Genetics in January 1968. Two other prototypes were delivered to John Amy at Purdue University and Carl Djerassi at Stanford University. Based on the feedback from these initial installations, many improvements were made in the Model 1015, especially in the single-jet separator design that had been given to Finnigan by Stenhagen (the Ryhage jet separator used in the LKB 9000 was a dual-stage design), which took almost 2 years to perfect.

Bob Finnigan became aware of the power of GC/MS in combination with the results he saw from the DS designed and built by Reynolds and Tim Coburn at Stanford.[63] Although Hites and Biemann had earlier reported a system to deal with the acquired data from a GC/MS system,[38] the Reynolds and Coburn system for the TQ mass spectrometer along with a similar system for magnetic-sector instruments developed by Jack Holland and Chuck Sweeley at Michigan State University[64] were the first DSs that actually controlled the mass spectrometer and also stored the data. The Stanford GC/MS DS led Finnigan to enter into an agreement with a new company, Systems Industries, Inc. (Sunnyvale, CA), to commercialize the Stanford system and become the first commercial GC/MS DS – the System 150. Finnigan accepted its first order for a computerized GC/MS system in 1968 from Evan Horning at the Baylor College of Medicine (Houston, TX).

Initially, the System 150 was sold only by Finnigan Corporation. The data consisted of a Digital Equipment Corporation (DEC) PDP-8 minicomputer with 4K words (12-bit words) of core memory, a magnetic tape system (a LINC, Lincoln Laboratories at MIT, tape) designed specifically for the PDP-8, a standard ASR 32 teletype for input and output of text information as well as the ability to load programs through a punched paper tape, and a Houston Instruments digital plotter for the output of bar-graph mass spectra normalized to the most intense peak and reconstructed chromatograms (total ion current and mass). The DS had an interface that would convert digital instructions into analog signals used to tell the mass spectrometer which m/z range to scan, the time interval for each scan, the total analysis time, the magnitude of the radiofrequency (RF) and direct current (DC) voltages for each individual m/z value, and other factors associated with data as well as taking the analog data from the mass spectrometer that represented m/z values (based on calibration with a compound that produced ions of known m/z values) and ion abundances. These analog signals from the mass spectrometer were converted to digital values that were used to display the acquired data as spectra or reconstructed chromatograms. The computer and magnetic tape, along with the interface, were fitted into an electronics rack that was 19 in wide, 60 in high, and 30 in deep. The System 150 went on to be a general-purpose GC/MS DS sold by Systems Industries as well as several manufacturers of GC/MS instrumentation on an original equipment manufacturer (OEM) basis.

The System 150's capabilities were expanded and refined through the use of third-party software such as the Biemann computerized library search of mass spectral databases[65] and use of the Tektronic's electronic storage terminal for graphical display (both developed at the Battelle Columbus Laboratories), and data analysis and acquisition software specific to sector-based instruments developed at Michigan State University. The System 150, later marketed by the French GC/MS manufacturer Nermag (originally Riber) as the RDS 400, also took advantage of new hardware features such as disk storage that replaced the slower and lower capacity magnetic tape systems. The Riber 400 remained a reliable and competitive GC/MS DS through the mid-1980s. Because all of the software was developed using the PDP-8's assembly code and the system was capable of either acquiring or processing data, but not both at the same time on a single computer, it was very fast. It has only been in the last 2–3 years that GC/MS data processing has achieved the speed of the System 150/Riber 400, and this has been due to the very fast computers with extremely large amounts of random access memory (RAM).

There were two additional third-party DS companies that appeared in the late 1970s: INCOS (acronym for Instrument Company Operating System) and Teknivent Corporation. The INCOS DS was originally designed as a retrofit to sector-based instruments. The INCOS used a Data General minicomputer with a custom disk operating system called IDOS (another acronym) that allowed for simultaneous data acquisition and analysis. The data analysis features were unique with some rather spectacular graphics displayed on the Tektronic's graphics

Figure 10 A partial display of the three dimensions of chromatographic/mass spectrometric data.

terminal. These graphics included a three-dimensional plot of the spectra along the z-axis, a spectrum number on the x-axis, and an m/z intensity on the y-axis (Figure 10). The INCOS DS introduced a new era in the comparison of a spectrum of an unknown substance with those contained in a mass spectral database. The INCOS library search algorithm became the basis for most commercial DSs used with current instrumentation. INCOS was sold to Finnigan Corporation in the late 1970s. Finnigan quickly adapted the system for use with its line of TQ mass spectrometers. The INCOS DS gave Finnigan a significant advantage in its second generation of GC/MS instrumentation – the 4000 series.

The INCOS DS remained an exclusive of the Data General minicomputer long after many manufacturers had shifted DS developments to the IBM PC-type computer. This unusual longevity is rumored to have resulted from a settlement between Data General and Finnigan over the fact that the INCOS' unique disk-operating system, IDOS, was an infringement of copyrights held by Data General on disk-operating systems.

Teknivent was another company that joined System Industries/Riber and INCOS in competition for the after-market DS business. Teknivent developed a series of DSs that were based first on various minicomputers and then on the IBM-type microcomputers (PCs). They were one of the first companies to introduce a GC/MS DS on the PC using the IBM PCXT ca. 1983. Teknivent was the only instrument company to use the IBM OS2 operating system, which allowed for control of multiple gas chromatograph/mass spectrometer systems from a single computer. A significant number of these DSs were sold through the late 1980s and early 1990s as replacements for minicomputer systems used with the Riber R10-10, Finnigan 3000 and 4000, and INCOS 50 series of GC/MS instrumentation as well as many of the Hewlett-Packard instruments that used UNIX and Pascal-based DSs. This St Louis, MO-based company ceased doing business around 1996, and its assets were acquired by ProLab Resources (Madison, WI), a company that had been functioning as a third-party software developer for GC/MS data analysis systems.

Although none of these original third-party DS manufacturers exist today (with the exception of Teknivent within ProLab Resources), the concept of after-market DSs is still very strong. Among the companies at the end of the second millennium, there is one that produces a system primarily for sector-based instruments – MSS in Manchester, UK. MSS also has a system for quadrupole instruments. Los Gatos Circuits (LGC, San Jose, CA) markets a DS for some models of TQ instruments that is produced by SysNet Corporation (Scotts Valley, CA). In addition, Shrader Analytical (Detroit, MI) has produced a system that is OEM to JEOL USA and sold as an after-market system for sector-based instruments.

Over the next few years, following the introduction of Finnigan's first instrument, the field of GC/MS grew at an exponential rate largely fueled by a very active market in environmental chemistry. The Finnigan Model 1015/System 150 was the first commercial GC/MS DS and was introduced at the Fall ACS meeting in New York City in 1969. A short time later, Hewlett-Packard introduced an instrument also based on the TQ mass spectrometer, which helped to legitimize the TQ technique for organic MS. Although the growth has been nothing short of spectacular for the past 30 years, the start was slow with Finnigan selling only one Model 1015/System 150 in the 18 months after the New York introduction.

Hewlett-Packard and Finnigan dominated the GC/MS market, largely owing to the simplicity of operation of the TQ and the continued advancement of the DS. The LKB 9000, which had dominated the GC/MS market especially in biotechnology, in the last half of the 1960s fell into rather quick obscurity owing to the lack of a computerized DS. The major European and Japanese mass spectrometer manufacturers of the early 1970s concentrated on magnetic-sector mass spectrometers that had GCs as inlets. These efforts were never very successful because of the higher cost of the sector instruments, and insufficient emphasis was placed on the DS. The only other serious attempt at a magnetic-sector-based GC/MS system was made by DuPont with an instrument using a fixed-field magnet and a variable accelerating voltage. DuPont had acquired the mass spectrometer pioneer CEC from Bell & Howell in a last attempt to make the company competitive in the GC/MS marketplace, but it failed, largely owing to problems of source arcing at the high voltages required (in excess of 12 500 V) to look at ions below m/z 43.[66]

Hewlett-Packard and Finnigan continued to emphasize the DS as being as significant as the mass spectrometer; however, Hewlett-Packard began to look at the technique

as one for the chromatographer rather than the mass spectrometrist. This approach led to the development of the benchtop GC-MS, which has dominated the market since 1982 with the introduction of the HP 5970. This benchtop GC-MS was followed by the introduction of an IBM PC-based DS for the Finnigan benchtop ITD™ 700 in 1984. Hewlett-Packard introduced the PC-based DS for the 597X family of instruments (5970, 5971, 5972, and 5973) in 1989.[67] Currently, Hewlett-Packard has more GC/MS units in service than all other types of mass spectrometers combined, and the TQ m/z analyzer has long ago replaced the magnetic-sector m/z analyzer as the mass spectrometer of choice for GC/MS.

After Finnigan and Hewlett-Packard became dominant in the field of GC/MS, other companies have developed popular products such as the Shimadzu QP 5050 and the Perkin-Elmer Qmass and Turbomass, both based on the transmission quadrupole. Finnigan introduced the ITD™ 700 in 1984 based on the QIT m/z analyzer. Through a technology purchase and an initial OEM agreement, Varian advanced Finnigan's internal ionization QIT to the point of being a dominant player in today's GC/MS market. More recently, LECO Corporation has introduced a rapid acquisition GC/MS system based on time-of-flight mass spectrometry (TOFMS) technology developed at Michigan State University that will acquire 1000 spectra per second over an m/z range of 1000 and will allow for greatly reduced analysis times. Micromass/Waters introduced a GC/TOFMS system at the 1999 Pittsburgh Conference on Analytical Chemistry and Applied Spectroscopy (Orlando, FL) that has the conventional EI and CI sources in addition to an FI source. This instrument has the capability of exact mass measurements. The magnetic-sector-based mass spectrometer has returned to the GC/MS field with a reverse-geometry, double-focusing, exact-mass-measurement 'benchtop' instrument introduced in the mid-1990s – the JEOL GCmate.

Another contributing factor to the success of GC/MS was the development of CI,[68] a technique that imparted far less energy to the analyte molecule when ionized in the gas phase, in the mid-1960s. CI is a process where a reagent gas present in the mass spectrometer's ion source at a relatively high pressure [0.1–1 Torr (in the internal ionization quadrupole ion-trap (I^2QIT) mass spectrometer, this type of CI is carried out in a time domain at reagent gas partial pressure of $\sim 10^{-5}$ Torr)] is ionized by a beam of high-energy electrons. Through this initial EI of the reagent gas and subsequent reactions of the resulting ions with reagent gas molecules, reagent ions are formed (Figure 11) that will then ionize the analyte through one of several mechanisms (Figure 12) resulting from ion–molecule reactions. In many cases, this will produce an ion that is directly related to the intact molecule (e.g. a protonated molecule). This information can be complementary to an EI mass spectrum, especially when there is no molecular ion peak in the EI spectrum.

Figure 11 EI of methane followed by fragmentation of the molecular ion. The methane molecular and fragment ions then react with molecules of methane (ion/molecule reactions) to produce various types of methane reagent ions used to bring about the CI of an analyte.

The technique of MS/MS, developed in the mid-1970s, has been very important in GC/MS.[69] The triple quadrupole using an RF-only TQ position between two traditional scanning TQ m/z analyzers[39] or tandem-in-time analyses with the QIT m/z analyzer[70] has allowed for more and more accurate information about analytes that can be ionized in the gas phase using GC/MS.

2.4 Liquid Chromatography/Mass Spectrometry – A Slow Start – But a Fastcomer in the Backstretch

LC/MS is a more-encompassing term than GC/MS. In GC/MS, samples are introduced into the mass spectrometer as analytes in the gas phase from either a packed or capillary column (or one of the several iterations of the capillary column), where they are ionized. In LC/MS, analytes can enter the mass spectrometer in solution from an analytical (usually 4.6 mm ID) or capillary ($\leq$2 mm ID) LC column via flow injection, or through direct infusion of a liquid that flows because of a pump [e.g. microelectrospray (microES)] or due to electro-osmotic flow [e.g. nanoelectrospray (nanoES)], or as components from capillary electrochromatography or capillary electrophoresis. In some cases, these analytes are ionized in the mass spectrometer, and in others (e.g. ES or one of its adaptations: microES or nanoES), they enter the mass spectrometer as solvated ions. Whereas in GC/MS the chromatographic mobile phase is an inert single component (usually helium or hydrogen) and the only concern is its contribution to the pressure inside the ion source, the mobile phase in LC/MS is often a complicated mixture of solvents and nonvolatile substances, some of which may be present to react purposefully with the analytes to improve chromatographic separations but interfere with the formation of gas-phase ions. All of this makes LC/MS a much more complex issue than ionization of gas-phase analytes.

Charge transfer (the reagent ion, missing an e^-, takes an e^- from the analyte)

$$CH_4^{+\bullet} + RH \longrightarrow RH^{+\bullet} + CH_4 \qquad M^{+\bullet}$$

Proton transfer (most common when the analyte molecule has a higher proton affinity than the reagent gas. The analyte takes H^+ from the reagent ion)

$$CH_5^+ + RH \longrightarrow RH_2^+ + CH_4 \qquad [M+1]^+$$
$$C_2H_5^+ + RH \longrightarrow RH_2^+ + C_2H_4$$

Hydride abstraction (the reagent ion has a high hydride affinity, the ability to remove a H^- from the analyte molecule)

$$CF_3^+ + RH \longrightarrow R^+ + CF_3H \qquad [M-1]^+$$
$$C_2H_5^+ + RH \longrightarrow R^+ + C_2H_6$$

Collision-stabilized complexes (occurs when the PA of the analyte and reagent gas are comparable. The reagent ion becomes attached to the analyte. When methane is used, this series, $[M+1]^+$, $[M+29]^+$, and $[M+41]^+$, is a very good confirmation of molecular weight)

$$C_2H_5^+ + RH \longrightarrow (C_2H_5 : RH)^+ \qquad [M+29]^+$$

$$C_3H_5^+ + RH \longrightarrow (C_3H_5 : RH)^+ \qquad [M+41]^+$$

Figure 12 Types of ion/molecule reactions that result from positive-ion CI.

GC/MS was an established technology within the first 5 years after the introduction of the first commercial instrument – the Finnigan Model 1015/System 150 in 1969. By the end of the 1970s, GC/MS dominated the field of MS, and the TQ mass spectrometer was an accepted technology. LC/MS has been a different story. The interface posed a more difficult problem. Dealing with a gas load of 20–30 mL min^{-1} (typical carrier gas flow rates for packed columns used with early GC/MS instruction) was very different from 550 mL min^{-1} of gas (at atmospheric pressure and room temperature) produced from a flow of 1 mL min^{-1} of acetonitrile eluting from an LC column. It was also important to the early developers of LC/MS that the spectra be produced by EI. The EI spectra requirement meant that the analyte had to be in the gas phase at some point; therefore, the technique would have been limited to analytes that were not in an ionic form in the LC eluate.

The earliest attempts were made by Patrick Arpino and Fred McLafferty with a technique called 'direct liquid introduction' (DLI)[71] (Figure 13). These attempts were carried out by using EI and the relatively new technique of CI. Attempts were made to use the volatilized mobile phase of the LC process as a reagent for a CI process.

Following attempts at the DLI (which were never very successful from a commercial standpoint) came the moving-belt interface (Figure 14), pioneered by William McFadden at Finnigan Corporation.[72] This technique did not offer a great deal more usable data than DLI; however, it was commercially much more successful because the ion-source pumping requirements were much less. The limitation of a somewhat volatile analyte remained.

Figure 13 A schematic illustration of a direct-liquid-inlet probe for LC/MS. (Courtesy of Hewlett-Packard (now Agilent Technologies), Palo Alto, CA.)

A technological success for an interface between a LC and a mass spectrometer was the original work on API done by Evan Horning's group at the Baylor College of Medicine (Houston, TX) in the mid-1970s.[73] This technique involved the formation of ions of the intact analyte through a CI process that was cried out at atmospheric pressure. At the time of this development, not much acceptance was forthcoming because only molecular weight information was generated. The customary fragmentation data used for structure elucidations was missing. Horning called this technique 'API'. API is the term now applied to the two techniques involved with

Figure 14 An illustration of the moving-belt LC/MS interface. (Courtesy of Finnigan Corporation (now ThermoQuest Corporation), San Jose, CA.)

getting ions into the gas phase at atmospheric pressure: APCI and ES.

The APCI technique requires the analyte to be volatile enough to allow for a gas-phase ion–molecule reaction to take place, which means that the analyte cannot be in the ionic phase in the LC eluate. This volatility requirement, coupled with the fact that for the most part only molecular weight information resulted, led to an initial limited use. The technique required a lot of pumping that added to the cost and complexity of commercial instrumentation. APCI did not become popular until after the development of the triple-quadrupole mass spectrometer, which allowed for MS/MS of these ions representing the intact molecule, thereby producing structural information about the analyte. APCI also became a good companion for ES because both were atmospheric techniques and used similar interfaces to the mass spectrometer.

Today, APCI and ES dominate LC/MS instrumentation. The only other LC/MS technique that was commercially viable at the end of the 20th century was the particle beam interface developed by Ross Willoughby and Robert Browner in the mid-1980s.[74] This technique allows for acquisition of EI and CI mass spectra of analytes in the gas phase after a partial desolvation using a heated drying gas and momentum separator. Clumps of moist analyte molecules are propelled onto a heated plate located in the ion source of the mass spectrometer. These moist clumps striking the heated plate result in the volatilization of the analyte molecules, allowing for their subsequent ionization in the gas phase. Although this technique can yield more structural information about the analyte, it has much poorer sensitivity than ES or APCI and has the limitation of the volatile requirement for the analyte.

During the mid-1980s, two different independent approaches were made to LC/MS that used the DI technique FAB by Y. Ito[75] and Richard Caprioli.[76] These techniques were called 'frit-flow FAB' and 'continuous-flow FAB', respectively. Again, these were labor-intensive techniques and were far from allowing for routine analyses. However, at the time, this was the only technique that allowed for the analysis of nonvolatile thermally labile LC analytes such as polysaccharides, peptides, and oligonucleotides. These iterations of FAB have been replaced by ES.

Another abortive attempt at LC/MS was a technique called 'thermospray'. Thermospray was pioneered by Marvin Vestal,[77] currently at PE Biosystems and at VesTech and the University of Houston at the time this technique was developed, in the early 1980s. The original form of this technique (filament-on) was similar to the DLI. Later, a technique was serendipitously developed called 'filament-off' for the analytes that were in an ionic form in the LC eluate when ion current was observed after a failure of the filament. Even though the thermospray technique was also labor intensive and fraught with many difficulties, it had a reasonable commercial success in that investigators were desperate for tools to analyze substances separated by LC.

Beginning in the mid-to-late 1980s with publications by John Fenn[78] and Jack Henion,[79] the technique of ES started to evolve. After Fenn, Mathias Mann, and C.K. Meng published an article entitled 'Protons or Proteins – A Beam's Beam'[80] in 1988, ES and its companion technique of APCI underwent a logarithmic growth in improvement, numbers of applications, and advancements in the commercial instrumentation. ES went from being a research-laboratory curiosity to one of the most widely used tools in biotechnology.

Techniques such as continuous-flow fast atom bombardment (CF-FAB), currently being developed, will take LC/MS into expanded areas of use in organic chemistry and biotechnology.

2.5 Desorption/Ionization

DI is the term applied to the processes by which mass spectrometrists '... make elephants fly'.[81] DI is a technique in which ions are formed in other than the gas phase, and the ions are then desorbed from the matrix where they are formed into the gas phase. Currently, the two most widely used and popular DI techniques are MALDI and ES. However, although not as widely employed, the techniques of FI and FD and also FAB are still in use. A new TOF-based GC/MS system was introduced by Micromass at the 1999 Pittsburgh Conference on Analytical Chemistry and Applied Spectroscopy (Orlando, FL), which had an FI source available as an option.[82] It is still common to find abstracts in almost every issue (once every 2 weeks) of *CA Selects Plus MS* (a publication of the Chemical Abstracts

Service of the ACS) on the use of FAB or CF-FAB in LC/MS applications.

Another important DI technique that is still widely used is DCI. This probe technique is especially suitable for use with TQ mass spectrometers. Vinca Promacvich, organic analytical facilities manager in the Department of Chemistry, Columbia University, says, ''When these organic chemistry students bring samples ('pure' or mixtures for GC/MS analysis), the first thing I do is try them [the samples] with DCI. If I do not get usable spectra, then I will not take the chance of ruining a GC column or contaminating the ion source by trying the analysis of something that is probably a crystallized inorganic salt rather than the suspected reaction product.''

2.5.1 Field Desorption and Field Ionization

The first DI technique to be seriously considered in MS was FD. FD is an ionization technique by which analyte ions are desorbed from the surface of one of the two electrodes used to produce an electrical field. This technique was the first to allow the determination of the mass of analytes that were nonvolatile or thermally labile. FD uses specially prepared sample emitters that allow for the production of protonated molecules (MH^+). Because single-charge ions are produced, the mass limitations at the time of the development were determined by the maximum m/z value of the mass spectrometer. Formation of ions via an electrical field had its origin with field-ion microscopy developed in 1951 by E.W. Müller in Germany. The first developments involving FD were by R. Gomer and M.G. Ingrahm.[83,84]

The technique of FI of gas-phase analytes was an outgrowth of the development and study of FD. FI is a technique, rivaling CI, that results in a high abundance of ions representing the intact molecule. Unlike CI, which produces even-electron protonated molecules (MH^+), FI produces odd-electron molecular ions ($M^{+\bullet}$). In FI, ionization of an analyte molecule in the vapor phase takes place in an electrical field (107–108 V cm^{-1}) maintained between two sharp points or edges of two electrodes. The technique of FI was developed by H.D. Beckey at the Institut für Physikalische Chemie der Universität Bonn (Bonn, Germany) in 1957.[85]

Becky has gone on to show additional developments in both the FD and FI techniques. His 1977 book *Principles of FI and FD MS* is considered the seminal reference for these techniques. According to a statement made by Ronald D. Macfarlane, developer of the Cf DI technique, ''FD opened the door for biological MS by demonstrating feasibility.''

FD is carried out with sample deposited from solution on tungsten filaments that have been activated by growing a dense matrix of needles of graphite on its surfaces. The process of preparing the filaments and introducing the sample without disturbing this delicate forest of needles is an art form in and of itself. Although FD was used to a large extent as the only technique for nonvolatile thermally labile analytes from its development in the 1960s, it was largely replaced with other less-tedious techniques such as FAB, DCI, and now MALDI and ES.

2.5.2 Plasma Desorption (^{252}Cf Desorption/Ionization)

The next DI technique to be developed was that pioneered by Ronald D. Macfarlane at Texas A&M. For the most part, the technique of ^{252}Cf DI (Cf DI) [or plasma desorption (PD)] remained a laboratory curiosity through its useful life. The dependence of PD on TOFMS was not sufficient to prevent the last US manufacturer of these instruments (CVC Corporation) from discontinuing their manufacture in the late 1970s. There was a single commercial attempt at a PD instrument in the 1980s by Bio-Ion in Uppsala, Sweden. The instrument was later marketed by Kratos Analytical, UK. Bio-Ion was later acquired by Applied Biosystems (now PE Biosystems).

The primary reason for the lack of popularity of Cf DI was the radioactive nature of the ionization source, which presented a significant safety and disposal problem for a number of laboratories.

PD was first reported in 1974 with results obtained from the nonvolatile compound sodium acetate. This report predicted the use of PD for larger nonvolatile molecules such as biopolymers.[86] Two years later, Macfarlane's group reported the analysis of a peptide with a molecular weight of 1881 Da.[87]

PD is accomplished by putting the analyte sample on one side of a nickel or aluminized Mylar® plate. On the other side of the plate is a 10 μCi ^{252}Cf source. Each fission event results in two products of nearly equal mass, each having energies of 80–120 MeV propelled in opposite directions. One triggers the start of the detector and the other rips through the sample holder to desorb intact adduct ions of the analyte molecule ($[M + H]^+$, $[M + Na]^+$, etc.). The ions are captured by the ion optics of a specially designed TOFMS instrument and are accelerated into its flight tube. Mass spectra are accumulated over a period of several hours depending on the signal strength of each event and the required signal-to-background for the analysis.

Macfarlane also developed the method of ES for the deposition of the sample on the PD sample holder.[88] Peter Roepstorff (Odense University, Denmark) became an outspoken proponent of the technique in support of Bio-Ion.[89]

The DI technique that showed mass spectra could be obtained from large peptides and proteins as well as other biologically significant substances such as

oligonucleotides was Cf DI, which was the genesis of bioanalytical MS. This DI technique is no longer in use, even in university research laboratories.

2.5.3 *Fast Atom Bombardment*

In an effort to use MS for the analysis of proteins, investigators attempted to get results by layering the purified protein onto a metal surface and then used a SIMS technique (see section 2.7.3) to desorb ions from the surface of this open-face sandwich. This was not very effective because the energy absorbed by the sample often resulted in sample decomposition. When secondary ions were produced using lower-energy bombarding ions to avoid damage to the top layer of the analyte and prolong the secondary ion current, the analytical ion current was significantly reduced resulting in poor detection limits. Also, the SIMS technique resulted in an ion current of a very short duration, which also affected the detection limit.

In a further attempt to obtain better results from the 'sputtering' mass spectral ionization techniques, Mickey (Michael) Barber in the Department of Chemistry at the University of Manchester Institute of Science and Technology in the mid-1970s began to look at the possibility of using accelerated atoms to bombard the sample as opposed to ions.[90] The decision to use atoms as opposed to ions was born out of the desire to use a double-focusing mass spectrometer that required ion acceleration of ~8 kV. This technique was effective but, for the targeted organic analytes, suffered from the same short duration of ion current that had been observed with SIMS. When Barber's group undertook this research, they had set the goal of developing a new ion source that met the following criteria: (1) produces ions at room temperature, thereby eliminating the necessity for volatilizing the analyte prior to ionization; (2) the ionization process should result in both the abundance of molecular ions to allow for molecular weight determination and fragment ions that can be used to deduce the analyte's structure; (3) the mass spectrum resulting from this ionization process should have a sufficient lifetime to allow for techniques such as metastable ion detection, which can be time-consuming in a double-focusing mass spectrometer; (4) the detection limit should be such that structural information can be obtained from as little as 1 μg of analyte; and (5) the ionization technique should have the potential for easily and reproducibly generating mass spectra of analytes that have proved problematic or impossible by other types of ionization.

After half a decade of research and based on curious observations of sample contaminants by pumping fluids (e.g. Apiezon oils, Santovac 5, and Convalex 10) and glass–glass vacuum sealants such as siloxane stopcock greases,[91] a way to prolong the ion current was found

Figure 15 FAB mass spectrum of the tripeptide alanylleucylglycerine (molecular weight 259) produced with 7 KeV xenon atoms. While smaller than the peptide originally analyzed by Barber et al.[92] (Tyr-Gly-Gly-Phe-Met, molecular weight 573), this spectrum illustrates the principle of FAB. Note the peaks representing ions that result from sodium addition to the analyte molecule. (Courtesy of B.L. Ackermann in the NIH Mass Spectrometry Facility at Michigan State University, East Lansing, MI.)

by mixing the analyte with a low-vapor-pressure viscous solvent. The first material found to be satisfactory for this technique was glycerine (glycerol) used to obtain the mass spectrum of a small peptide (methionine enkephalin, Figure 15).[92]

The genesis of FAB is well chronicled in an *Analytical Chemistry* A-pages article that appeared in 1982.[93] FAB was easily adaptable to existing TQ and double-focusing mass spectrometers although the best results were obtained using the sector-based instruments. FAB met all of Barber's objectives for a new ionization technique and was readily adopted by the MS community. A Boolean search of MEDLINE (http://www.infotrieve.com/freemedline/) for 'FAB' yielded 6 papers in 1981, 69 in the period 1981–1984, and over 325 in the period 1985–1989. This last number is far from the total number of publications that appeared using this powerful technique during that period. FAB also found immediate applications in the technique of MS/MS using both TQ and reverse-geometry double-focusing instruments (see section 2.6). FAB differed from either FD or PD in that it was easy to prepare sample, easy to use, and spectra could be obtained in a reasonable period rather than the hours or days required for PD. As soon as fragmentation spectra were being obtained from peptides, schemes for their interpretation were developed. FAB allowed for the more

realistic characterization of microorganisms by MS that was pioneered by Catherine Fenselau at the University of Maryland, Baltimore County.[94]

As a variation of FAB, the technique of liquid secondary ion mass spectrometry (LSIMS) was developed. Instead of the beam of neutral atoms being fired at the mixture of analyte and carrier, a beam of ions is used. For the most part, the same results are obtained. The LSIMS technique imparts more energy to the analyte. As described above under LC/MS, FAB proved to be a useful technique with dynamic separations as well as one that allowed for the analysis of purified samples. FAB was still in use at the end of the 20th century; however, it has largely been replaced by MALDI and ES.

2.5.4 Desorption Chemical Ionization

As MS developed, techniques evolved to introduce sample in all three physical states of matter (gas, liquid, and solids). Some solids had sufficient volatility that results could be obtained by putting the material on the end of a probe placing the probe tip in the mass spectrometer's ion source and heating the probe to produce a vapor that was ionized. In some cases, this proved to produce better quality spectra than could be obtained by volatilizing the sample outside of the ion source.[95] In 1973, Fred McLafferty introduced the technique of placing a sample on a probe and heating it while subjecting it to an ion plasma produced in a CI source by showing a spectrum of a nonderivatized peptide (VAAF) with a large protonated molecule $(M + H)^+$ peak and other peaks that were used to determine the sequence.[96] This variation of the technique used to introduce samples on a direct-insertion probe (or solids probe) has been called 'direct CI', 'in-beam', 'direct exposure', and 'desorption CI'.[97] The last has been the accepted name for a number of years.

Desorption electron ionization (DEI) has also been used. The probe used for DCI and DEI is called a 'direct-exposure probe'. The direct-exposure probe is distinguished from the solids probe in that the sample is placed on the outer surface of the probe, whereas the sample is placed in a hollow cavity at the tip of the solids probe. This hollow cavity is often similar to a short (5–10 mm long) melting-point capillary tube.

Today's direct-exposure probes are constructed with a filament that can be rapidly heated. The physical shape, material of construction, and treatment of these filaments all contribute to the results obtained. A sample is dissolved in an appropriate volatile solvent, a drop of the solantoin is placed on the filament so that the filament is fully and evenly coated, and the solvent is then evaporated (Figure 16). The filament on the end of the probe is passed through the vacuum lock into the ion source of the mass spectrometer. A current is passed through the filament, which results in rapid heating. DCI takes place when a CI plasma is present, and DEI results when only a beam of electrons is used for ionization.

Figure 16 Filament used with the DCI probe of the Nermag R10-10 series of TQ mass spectrometers. (Courtesy of Scientific Instrument Services, Inc., Ringoes, NJ.)

The exact mechanism of this ionization has never been clearly explained. Evidence has been shown that indicates the intact analyte is desorbed from the surface of the filament, and ionization takes place in the gas phase.[98] This evidence supported an approach that used rapid heating. However, the difference in ion current obtained with different reagent gases indicated that the ionization was taking place on the surface of the filament, and the ions were then desorbed into the gas phase.[99] DCI is especially applicable to use with TQ mass spectrometers. It is unclear whether it was a combination of filament physical design and manufacturing material or factors pertaining to ion-source potentials, but results obtained using TQ instruments appeared to be significantly better than those obtained with sector-based instruments. DCI will produce mass spectra from nonderivatized sugars and other organic compounds that are thermally labile.

DCI produced spectra for many compounds that had been unsuccessfully ionized by FD. One of the more significant examples was the mass spectrum of brevetoxin B obtained by Koji Nakanishi at Columbia University in the mid-1980s on a Nermag R10-10 TQ mass spectrometer (Figure 17).[100] The Nermag R10-10's DCI probe used the coiled filaments shown in Figure 16. These filaments were constructed of a thoriated tungsten. This instrument, using this particular design, produced some of the best DCI spectra obtained on a commercial instrument. This particular technology is still commercially available through ThermoQuest's Automass Multi combination GC/LC/MS system.

DCI was developed and matured in the same time frame as FAB. Both techniques were amenable for

Figure 17 DCI of mass spectrum of brevetoxin B obtained by Koji Nakanishi at Columbia University in the mid-1980s on a Nermag R10-10 TQ mass spectrometer. (Courtesy of Koji Nakanishi.)

compounds that were thermally labile and/or nonvolatile. DCI has been a very good technique for use with TQ mass spectrometers, which are more limited in their maximum m/z detectability than double-focusing instruments. FAB is the preferred technique for proteins and peptides, whereas DCI works nicely with 1–5 saccharide sugars and coordination complexes.

2.5.5 Matrix-assisted Laser Desorption/Ionization

MALDI is a technique by which an analyte is mixed with an energy-absorbing matrix. Analytes are usually of high molecular weight (>2 kDa), and the matrix is usually of a much lower molecular weight (~0.5 kDa or less). Each is separately introduced into a shallow well on a flat plate in solution, where the two components are mixed through the natural mixing of the solutions. The solvent is evaporated leaving a solid mixture of matrix and analyte. This mixture is then subjected to a blast from a laser [both IR and UV lasers have been used]. The matrix molecules absorb the energy of the laser shot (Figure 18a–c). The energized matrix molecules are then responsible for the formation of protonated molecules that are passed into the gas phase, partly due to the ablation of the sample caused by the impact of the laser. This technique was found to produce ions of intact molecules that were mostly single-charge ions, but there is also the possibility of double- and triple-charge ions. The mass spectrum can also contain peaks representing dimers and trimers of the analyte (not very common). MALDI was developed by two German scientists (Franz Hillenkamp and Michael Karas) working at the Institute für medizinische Physik und Biophysik, Universität Münster (Münster, Germany).[101]

Figure 18 An illustration of the MALDI principle: (a) the chemical structure of a common matrix molecule for MALDI; (b) an artist's conception of the cocrystallized decomposition of a mixture of matrix molecules and protein analyte on a probe tip; (c) illustration of the operating principles and a typical configuration of a MALDI instrument with a TOF mass spectrometer.[7]

MALDI allows the detection of ions representing intact proteins and other biopolymers that had masses in the tens to hundreds of kilodalton range. The fact that MS could be used to determine the mass of such substances was the good news. The bad news was that most of the mass spectrometers currently in use at the time MALDI was developed could not be used to separate ions of such high mass-to-charge ratios as experienced in this type of analysis. The upper m/z limit of the sector-based mass

spectrometer is a function of the maximum magnetic field that could be produced and still be stable. The instruments that rely on RF (TQ and QIT mass spectrometers) are limited by the maximum amplitude that could be obtained for a given frequency before the wave will break up. The only mass spectrometer that was not affected by one of these limits of the physics involved with the ion separation is the TOF mass spectrometer. Unfortunately, TOFMS instruments had fallen into the realm of an historical curiosity by the time MALDI was developed. Just a few years earlier, the only manufacturer of TOFMS instruments had stopped their production. There was little or no interest on the part of research laboratories in the USA or Europe in developments of TOF. There was still a fairly active interest in TOFMS in what was then the Soviet Union (now Russia and some of the countries just to the west of Russia). The power and advantages of MALDI resulted in reassurances in TOFMS to the point that many new applications have been developed for this MS technique. At the end of the 20th century, TOFMS was not only important to MALDI MS but also found uses in inductively coupled plasma mass spectrometer (ICP-MS), GC/MS, ES and APCI LC/MS, and SIMS used in surface analyses.

FAB was the gleaming new technology that dominated MS throughout the 1980s. MALDI has been the technique of the 1990s and, along with ES, has largely replaced FAB even though *Analytical Chemistry* did publish a review of commercially available FAB instrumentation as late as October 1997.[102]

2.5.6 *Electrospray*

Unlike all the previous types of DI, ES is unique in that the mass spectrometer is not necessarily involved in the ionization process. All the other DI techniques involve the formation of ions in the condensed phase by some process in the ion source of the mass spectrometer followed by the desorption of these ions into the gas phase. In ES, the analyte enters the mass spectrometer in solution already in an ionic state. Although the exact mechanism of ES is still widely debated,[20] it is generally agreed that solvated ions in charged droplets are desolvated in the interface of the mass spectrometer, which is why some people do not call the process ES 'ionization'. If ionization is a process of forming ions, then ES should not be called ionization; if ionization is a process by which ions are put into the gas phase, then ES is an ionization process.

The technique of ES, popularized in the last decade of the 20th century, has a long history that goes back to the 1930s.

2.6 Types of Mass (m/z) Analyzers

The part of the mass spectrometer used to separate gas-phase ions according to their m/z values is the mass analyzer. Mass analyzer is the traditional terminology. This term was satisfactory when used with instruments that existed before the 1990s because almost all encountered ions that had only a single charge. The term mass and m/z were used interchangeably, which led to labeling the x-axis of spectra with terms that were units of mass. After the popularization of ES, the multiple-charge ion became more commonplace; and, while always problematic, labeling the x-axis of a mass spectrum with unit-of-mass terms became a potential for conveying incorrect information. As an example, the DS accompanying an LC/MS instrument featuring an ES interface introduced in 1996 had the x-axis of all the spectral displays labeled 'amu'. Amu was not only an incorrect term (owing to its replacement with the symbol u in 1962) for mass, but the use of any term or symbol for a unit of mass on an axis that should have been labeled m/z, especially for spectra that contained peaks primarily representing multiple-charge ions, was also unconscionable.

Mass (m/z) analyzers can be divided into two broad categories: (1) those that in some way isolate ions of individual m/z values from a beam – beam-type instruments; and (2) those that store ions of all m/z values and detect ions through some process of single m/z isolation – traps. Magnetic-sector, double-focusing, TQ, and TOF mass spectrometers are beam-type instruments. QIT (both external and internal ionization variations) and ICR mass spectrometers are traps.

2.6.1 *Magnetic-sector Mass Spectrometer*

Magnetic-sector mass spectrometers use only a magnetic field to separate ions according to their m/z values (Figure 19). These instruments are referred to as single-focusing mass spectrometers. They are capable of separating ions that differ in one m/z unit over a range from 1 to $\sim$700 m/z. These types of instruments have been used as residual gas analyzers (RGAs) for analysis of elements, as isotope-ratio mass spectrometers, and as general analytical mass spectrometers for organic compounds. As one of the first mass spectrometers designed specifically for use in GC/MS, the LKB 9000 was based on a single-focusing magnetic sector. Owing to the inability of these instruments to acquire sequential mass spectra rapidly because of the hysteresis inherent in electromagnets and the complexity of the electronics resulting in a high initial cost and difficulty of operation, these types of instruments quickly dropped from commercial popularity for use in hyphenated techniques such as GC/MS when the TQ GC-MS was introduced in the late 1960s.

The explosion of new mass spectrometer manufacturers that came about after World War II resulted in several popular models of single-focusing magnetic-sector instruments. These instruments included the AEI (name

Figure 19 A graphic illustration of a single-focusing magnetic-sector mass spectrometer.

of Metropolitan Vickers parent company, Associated Electrical Industries, after 1960; see below) MS-2, MS-3 and MS-5; the MAT-Atlas CH-4 and CH-5; and the CEC 21-103C and 21-130.

2.6.2 Double-focusing Mass Spectrometer

Double-focusing mass spectrometers use a magnetic field to select ions based on their m/z values and an electric field to select ions based on their energy. These instruments became the workhorse of MS from the 1930s through the end of the 1970s. These instruments are capable of separating ions with very small differences in m/z values allowing for the determination of the elemental composition of the ion based on these millimass measurements. CEC was the first commercial manufacturer of double-focusing mass spectrometers beginning before World War II. After World War II, manufacturers and instrument designs sprung up in the UK (Metropolitan Vickers delivered its first instrument in 1946 in Manchester, UK); Germany [Mes und Analysen-Technik (MAT) founded in 1947 in Bremen, Germany, as a subsidiary of Atlas-Werke AG]; and Japan (JEOL and Hitachi having existed as analytical instrument manufacturers before the war). At the beginning of the 21st century, a spinoff from Met Vickers (VG Analytical, now Micromass, Manchester, UK, a wholly owned subsidiary of Waters Corporation), JEOL, and the current owner of MAT (ThermoQuest) are the only commercial manufacturers of double-focusing mass spectrometers. Of these three manufacturers, JEOL is the only company that continues to have this type of mass spectrometer as its only mass spectrometer offering.

Names of the developers of the ion-optics systems used in double-focusing mass spectrometers are often associated with the instrument [e.g. Neir–Johnson (Figure 20), Mattauch–Herzog (Figure 21), and Bainbridge–Jordan].

The technique of MS/MS was developed as a result of forced metastable[103] ion formation between the two sectors of the double-focusing mass spectrometer. By placing (Figure 22) the magnetic sector as the first field following the ion source (reverse geometry) as opposed to the traditional configuration of having the electric sector as the first field (forward geometry), routine MS/MS experiments could be carried out.[104] This MS/MS technique remained popular until the development of the triple-quadrupole mass spectrometer (two TQ m/z analyzers separated by a third quadrupole operated in the RF-only mode used as a collision cell). MS/MS in the double-focusing mass spectrometer is an important selling feature of the JEOL LCMate and GCMate at the beginning of the third millennium. Although the TQ instruments remain dominant in MS/MS, the QIT is gaining in importance to this technique.

Many of the often-cited scientists[6,10] in MS had a great deal to do with the development of double-focusing

Figure 20 The ion optics of a Nier–Johnson double-focusing mass spectrometer with forward geometry.

Figure 21 The ion optics of a Mattauch–Herzog double-focusing mass spectrometer with forward geometry.

Figure 23 An illustration of the principle of TOFMS.

instruments. They were the people who were involved with applications development and ion optics. However, a number of other factors that took place behind the scenes were just as important. One of these factors includes the development of microprocessor electronics, which reduced the need for fine-tuning of the instrument by highly skilled operators. Another important factor was the development of the laminated magnet in the 1970s. This development helped to overcome the hysteresis problems with magnets that were the limiting factor in scan speed. The double-focusing mass spectrometer became a commercially viable instrument after World War II largely because of the advances in vacuum technology that grew out the use of the mass spectrometer as a preparative tool in the development of the atomic bomb.[2]

2.6.3 Time-of-flight Mass Spectrometer

The next gas-phase ion-separation technique in MS was involved with the development of the time-of-flight mass spectrometer (TOF-MS). Ions of different m/z values accelerated from a region such as an ion source into an evacuated tube will have different velocities, and therefore these ions will reach the end of this evacuated region at different times. By separating the times at which ion current is observed at a detector placed at the end of this evacuated region, it is possible to obtain a mass spectrum. Ions of the lowest m/z will reach the detector first (Figure 23).

The earliest report of experimentation with the concept of TOF for gas-phase ion separation was by William R. Smythe (US scientist) and Josef Heinvich Elizabeth Mattauch (Austrian physicist) in 1932.[105] According to an account by Robert W. Kiser in his book *Introduction to Mass Spectrometry and its Applications*,[6] the history of the early development of the TOF-MS involved a number of people.

While at the University of Pennsylvania (Philadelphia, PA), W.E. Stephens reported on the concept of the TOF-MS in an abstract appearing in the American Physical Society's program in 1946.[106] Some 7 years later, Stephens published a paper with M.M. Wolff with the same title as Stephens's 1946 abstract, 'A Pulsed Mass Spectrometer with Time Dispersion', which described the instrument they had built based on the TOF principle.[107] The seminal paper on TOFMS, 'TOF Mass Spectrometer with Improved Resolution', was published in 1955 by two researchers working for Bendix Aviation Corporation Research Laboratories in Detroit, MI.[108] This paper provides a detailed treatment of ion focusing in the TOF-MS. The Wiley–McLaren paper was considered to be of enough importance that it was republished in the *Journal of Mass Spectrometry* in 1997.[109]

According to a citation in Robert Cotter's book *TOFMS: Instrumentation and Applications in Biological Research* (ACS, Washington, DC, 1997), "... it was estimated that in 1962, one-third of the mass spectrometers in use in the United States were TOF instruments".[110] In his 1965 book, Kiser[6] states that the bulk of the US market had been provided by CEC (approximately 700 instruments). Considering these two statements, it is possible to believe that by the mid-1960s, only 10 years after Wiley and McLaren's paper, there were over 300 TOF mass spectrometers in use in the USA, and most of them had been manufactured by what later became known as the Bendix Corporation. In the mid-1960s, the future for the TOF-MS looked very bright. However, this was before the commercialization of the TQ mass spectrometer.

The Bendix Corporation was sold to Consolidated Vacuum Corporation, later known as CVC Products (Rochester, NY). Sale of TOF mass spectrometers declined to the level that CVC discontinued their manufacture sometime in the late 1970s to early 1980s. The popularity of the TOF-MS went through a period

Figure 24 Ion optics of the Kratos Kompact TOFMS instrument with a curved-field reflectron for improved ion focusing over a broad range of m/z values.

of rapid decline until the development of MALDI by Franz Hillenkamp and Michael Karas[101] in the late 1980s. In the decade that followed, the renewed interest in the TOF-MS resulted in an explosion of new developments, which included greatly improved resolving power, very rapid acquisition of data, and new ionization techniques such as Aviv Amirav's supersonic beams.[111] Beginning with the introduction of commercial MALDI TOF mass spectrometers in the mid-1990s followed by the explosion of TOF instrumentation in LC/MS, the TOF-MS has re-established itself as a significant factor in the industry (Figure 24). LECO Corporation (St. Joseph, MI) is a newcomer to MS through the acquisition of a GC/MS TOF system (Pegasus II) and an LC/MS TOF system (Jaguar) where both instruments represent new paradigms in their respective hyphenated techniques. Micromass and PE Biosystems both have an LC/MS product using TOF technology and an MS/MS hybrid instrument (TQ TOF). These instruments, which became widely used at the end of the 20th century, are just the genesis of the new TOF-MS. Within the next decade, the TOF-MS could supersede the TQ as the most used instrument in MS.

2.6.4 Transmission-quadrupole Mass Spectrometer

The TQ mass spectrometer uses a quadrupole field produced by a combination of DC and RF voltages that are applied to four conducting surfaces that have a hyperbolic cross-section. The first TQ mass spectrometers used four opposing round rods arranged parallel to one another to create this field. The TQ is often referred to as a 'mass filter' because it can be set to allow an ion of a single m/z value to pass through it while removing ions of all other m/z values from an ion beam. Quadrupole technology (which includes the TQ and monopole mass filters and the QIT) was first explored by Wolfgang Paul and colleagues at the University of Bonn (Bonn, Germany) in the early 1950s.[112] The initial paper on the quadrupole technology was followed by a detailed description of the theory.[113] Paul shared half of the 1989 Nobel Prize in Physics with the German-born American physicist Hans Georg Dehmelt, the developer of the Penning (magnetic) trap, 'for the development of ion-trap techniques'. The quadrupole ion trap was an outgrowth of his study of quadrupole fields. The monopole was commercialized in the 1960s by General Electric Corporation but never became very popular. The seminal reference on the quadrupole technology is Peter Dawson's *Quadrupole MS and its Applications* (Elsevier: Amsterdam, 1976; reprinted by the American Institute of Physics, Woodbury, NY, 1995).

The TQ mass spectrometer was very well suited for use with the emerging field of GC/MS. This m/z analyzer requires a much lower accelerating voltage EI and CI ion source than the sector instruments. It was smaller in physical size and much more suitable to rapid scanning and electronic control than the sector instruments. The TQ has a practical capability of producing unit-resolution spectra over an m/z range from 0 to ~4000.

The well-established mass spectrometer manufacturers of the time (which also included VG Analytical, a company that began some years after the others) were all committed to the magnetic-sector and double-focusing technology. Two companies new to MS (Finnigan Corporation, Sunnyvale, CA, now part of ThermoQuest Corporation, Austin, TX; and the California Instrument Division of Hewlett-Packard Corporation, Palo Alto, CA, now part of the HP spinoff Agilent Technologies, Palo Alto, CA) were the first to introduce GC/MS instrumentation based on the TQ mass spectrometer and are equally responsible for success of this type of mass spectrometer. At the end of the 20th century, there were more TQ mass spectrometers in use than all other types of mass spectrometers combined. In 1999, more GC/MS and LC/MS instruments using a TQ m/z analyzer were purchased than all other types of m/z analyzers combined.

An important note about the TQ that might have fallen from the pages of history if not for an article by Robert F. Finnigan on the history of TQ is that while Paul and his colleagues pursued this technology, Richard Post at the University of California Lawrence Berkeley Laboratory carried out independent research in the 1950s on the same technology.[37] Post did not publish or apply for patents on his findings. Other than information contained in his personal notebooks, the only record of his work is a University of California Radiation Laboratory Report (UCRL 2209) published in 1953.

Robert Finnigan (whose background was electrical engineering) actually began his quest for a TQ GC-MS at a process instrument and controls group that

he and a physicist colleague, P.M. Mike Uthe (from Lawrence Livermore National Laboratory and then Stanford Research Institute, SRI), founded for Electronic Associates Inc. (EAI, Long Branch, NJ), an analog computer company.[37,114] From the founding of this group within EAI in 1964 until 1967, Finnigan and his colleagues produced over 500 RGA instruments using the TQ. TQ mass spectrometers continue to have extensive use as RGAs. This RGA experience with EAI gave the founding group of Finnigan Corporation a solid background in TQ technology. Along with several others from EAI and the then general manager of Varian's chromatography business, Varian Aerograph, T.Z. Chu started Finnigan Corporation in January 1967. The goal of this company was to produce an easy-to-use, low-cost GC-MS based on the TQ mass spectrometer.

The first Finnigan GC/MS instruments sold for about $35 000, which was far less than any of the sector-based instruments. The TQ mass spectrometer was particularly suited to the newly emerging digital minicomputers. Finnigan Corporation, through a personal relation between Bob Finnigan and Ed Zschau (Stanford Business School Professor and early Silicon Valley entrepreneur) formed a relationship with Zschau's new company, System Industries, by which SI commercialized a DS based on the Digital Equipment Corporation's PDP-8 computer that had been in the Genetics Department at Stanford's Medical School.[63] Although the GC-MS was a low-priced item, adding the $50 000 for the DS produced a rather pricey item. Finnigan Corporation introduced the first GC-MS DS at the Fall ACS meeting in New York in 1969. This instrument was delivered to Evan Horning's group at the Baylor College of Medicine (Houston, TX).[37]

By the early 1970s, computerized GC/MS systems based on the TQ mass spectrometer were established analytical instruments. However, the $150 000 price for these instruments ($450 000 in the mid-1990s) prevented their wide use. Hewlett-Packard's (HP) efforts in the early days of TQ GC/MS have not been as well chronicled as those of Finnigan Corporation. HP's early efforts did not result in the same initial impact as Finnigan's, but the subsequent efforts of HP led to the affordability of the TQ-based GC-MS DS. Other companies played a key role with respect to the TQ mass spectrometer in the decade of GC/MS (1970s) and the decade of MS/MS (1980s). These companies are SCIEX (Toronto, Canada, now selling its instruments through PE Biosystems, Foster City, CA), Extranuclear Laboratories (Pittsburgh, PA, later known as Extrel, now operating as ABB Extrel and no longer providing analytical instrument systems), Riber/RiberMAG/Nermag (a French company still in France and owned by ThermoQuest), and VG Micromass. The only double-focusing instrument manufacturer at the time Finnigan and HP introduced their first instruments that were able to embrace successfully the TQ technology was VG Analytical (now operating as Micromass).

In addition to the continued manufacture of TQ m/z analyzers for use in GC/MS and LC/MS by ThermoQuest and Agilent Technologies, high-quality analytical instruments used for these purposes are also available from Waters/Micromass, Shimadzu, Perkin-Elmer Analytical Instruments (a division of EG&G), PE Biosystems/SCIEX, Hitachi, and others. The TQ is also used in RGAs and ICP mass spectrometers.

2.6.5 Quadrupole Ion-trap Mass Spectrometer

The QIT mass spectrometer was born out of the same Paul research that produced the transmission quadrupole; however, the QIT did not become a commercially viable instrument until the mid-1980s. The QIT uses a three-dimensional quadrupole field to store ions of multiple m/z values as opposed to filtering out ions of all m/z values except those of a selected value from an ion beam. The QIT consists of two end-caps electrically isolated on either side of a ring electrode placed between the two end-caps (Figure 25). This three-dimensional device has a hyperbolic cross-section.

The primary premise of any mass spectrometer has always been that the ions had to be separated in an area of low pressure. When ions were introduced into or formed inside the QIT maintained at traditional mass spectrometer operating pressures of 10^{-6}–10^{-10} Torr, it

Figure 25 An illustration of the I^{2}QIT mass spectrometer.

was found that while storage was very efficient, separating ions that differed by no more than an integer m/z value was not possible. Serendipitously, George Stafford and co-workers at Finnigan Corporation (San Jose, CA) found that by using a light buffer such as helium to maintain the trap at about 10^{-3} Torr produced excellent unit resolution and improved sensitivity.[115] This late-1982 discovery coupled with Stafford's earlier announcement of the mass-selective instability scan allowed the commercialization of the I^2QIT instrument. Ray March, in the preface to *Particle Aspects of Ion Trap Mass Spectrometry, Vol. 1: Fundamentals of Ion Trap Mass Spectrometry* (CRC, Boca Raton, FL, 1995), states that Stafford's mass-selective instability scan is as significant as Paul's work.

Stafford's initial breakthroughs of buffer gas use and the mass-selective scan mode led Finnigan to announce the first commercial GC-MS based on a QIT – the ITD™ 700 (an I^2QIT device) – at the 1983 Pittsburgh Conference on Analytical Chemistry and Applied Spectroscopy (Atlantic City, NJ). The plan had been to begin shipping instruments by mid-1983; however, shipments did not begin until December 1984. One of the problems that delayed shipment of the ITD™ 700 was mis-mass assignment for the molecular ion peak of some analytes that were unrelated to space-charge effects or ion/molecule reactions (both related to pressure, explained below). This mis-mass assignment was compound (ion) specific. The final solution resulted in the 'stretched' trap. This stretched trap did not result in a homogeneous quadrupole field, which had previously been thought to be a requirement for proper ion separation,[116] but was found as the only way to overcome this particular problem.

Even with many of the initial problems of bringing the I^2QIT GC-MS to market overcome in an intensive development cycle as described by John Syka[115] (ThermoQuest, San Jose, CA), the instrument met with a mixed reaction regarding its usefulness as a GC/MS instrument by those who received these first units. Because packed GC columns were predominant among GC users (especially in the USA), the interface between the GC and the mass spectrometer was a device that split the GC eluate with one part in 10 going to the mass spectrometer and the remainder going to atmosphere as a discard (the open-split interface). This split arrangement often resulted in a higher than desired amount of analyte in the trap. The amount of analyte was dependent on its initial concentration in the GC eluate. Ionization took place in the trap for a fixed time period (settable by the operator). If the amount of analyte was too high and a larger number of ions than could be stored in separated orbitals were produced, a space-charge mass spectrum would result with clusters of peaks on either side of the nominal m/z value peaks. There was no way to prevent this space-charge effect because the partial pressure of the analyte could not be controlled nor the ionization varied as a function of analyte partial pressure.

Unlike the beam-type mass spectrometers (sector, TOF, and TQ), which detected ions a few microseconds after their formation, the QIT stored ions for long periods (during the ionization time) in an area with analyte molecules. Depending on the ions formed by the analyte, this could lead to ion/molecule reactions that produced mass spectra that exhibited much higher than normal $[M+1]^+$ peaks. This phenomenon (sometimes referred to as self-CI) is analyte dependent. The most dramatic example of self-CI can be observed in the analysis of 2-octane (MW 128). This compound can produce a mass spectrum with essentially a single peak at m/z 129, which represents the protonated molecule. These ion–molecule reactions between an analyte and fragments of its molecular ions can easily be avoided in modern QIT instruments.

The problems with space-charge effects and self-CI resulted in a lot of criticism directed toward the ITD™ 700. On the other hand, the good sensitivity of this instrument was unprecedented. Users found detection limits lower than they had ever believed possible. Further development by Finnigan led to a modification in data acquisition that produced a variable ionization period based on the partial pressure of analyte. This development went a long way toward correcting the space-charge problems. Another significant factor about this particular fix was that it involved only a software modification. No additional hardware was required. Existing users could have their space-charge problems addressed with a software upgrade. Finnigan had entered into an OEM agreement with Perkin-Elmer Corporation (Norwalk, CT) whereby Perkin-Elmer sold the ITD™ 700 to customers that were not disclosed to Finnigan. While Finnigan upgraded all of its customers to the next generation of the I^2QIT software (ITD™ 800), unfortunately, Perkin-Elmer did not, thereby resulting in many dissatisfied initial ion-trap users.

In 1989, Finnigan sold rights to use their ion-trap patents to Varian Associates' Analytical Instrument Division (now Varian Corporation, Palo Alto, CA). This assignment of rights to Varian was followed by the introduction of the third-generation I^2QIT GC/MS system (Varian's Saturn and Finnigan's ITS40). By this time, the capillary GC column had replaced the packed column, and a number of significant hardware and software advancements had been made by Finnigan. One of the most significant was the ability to apply an RF voltage, which was at half the frequency of that applied to the ring electrode, to the two end-caps. This feature known as axial modulation greatly increased the storage capability of the trap, further reducing space-charge problems.[117]

The I^2QIT went on to demonstrate other advantages such as low-pressure CI (reagent gas partial pressure of 10^{-5} Torr compared with 0.1–1 Torr in beam-type instruments), MS/MS in time and MS^n, and selected ion storage. Some 16 years after the introduction of the first commercial QIT mass spectrometer, a GC/MS instrument using external ionization is available from ThermoQuest; an internal ionization GC is still produced as several models by Varian worldwide, and Hitachi manufactures and sells an internal ionization GC-MS in Japan; ThermoQuest has two models of a second-generation API (ES and APCI) LC-MS; and Hitachi and BrukerDALTONICS (in a joint marketing agreement with Agilent Technologies) produce an ES QIT LC-MS. Because of the multiple iterations of ion isolation followed by CAD, the QIT is of particular interest to LC/MS. For this same reason and the extreme good sensitivity, QIT technology is also very popular with GC/MS users. The QIT GC-MS is the instrument of choice for the analysis of air pollutants. The best reference for understanding the physics of the QIT is *Quadrupole Storage MS* by R.E. March and R.J. Hughes (Wiley, New York, 1989).

2.6.6 Ion Cyclotron Resonance and Fourier Transform Ion Cyclotron Resonance Mass Spectrometer

The ICR mass spectrometer is the other type of ion trap – magnetic as opposed to quadrupole. Whereas the quadrupole ion trap is referred to by the name of its original developer (the Paul trap), the ICR is called the Penning trap, a name given it by its developer, Hans G. Dehmelt.[118] Dehmelt's work with the development of the ICR, which began in 1955 at the University of Washington (Seattle, WA), led to his sharing half of the 1989 Nobel Prize in Physics with Wolfgang Paul. The ICR is a combination of the magnetron and the Penning ion source. Unlike the omegatron that uses a fixed-field magnet, the magnetron/Penning mass spectrometer uses a variable-field magnet.

The Fourier transform ion cyclotron resonance mass spectrometer (FTICR-MS) was developed by Allen Marshall and Melvin B. Comisarow when they applied Fourier transform algorithms to the mass separation technique of ICR in 1974.[119] The application of the Fourier transforms to detect ions separated by the ICR technique improved it to the point that the technique became of significant value to analytical chemistry. This instrument is capable of extremes in high-resolving power (Figure 26) and has proved to be of great value in ES LC/MS where the number of charges on an ion can easily be determined by counting the number of isotope peaks within one m/z unit.

The FTICR-MS requires the use of a superconducting magnet, which, depending on the magnet's field strength, can add significantly to the cost. The higher the field

Figure 26 An example of the utilization of the high resolving power of FTICRMS in determining the number of charge states on an ES ion. The number of isotope peaks that can be observed in a single integer m/z unit is equal to the number of the charges on the ion. (Reproduced by permission from D.H. Williams, 'Applications of Chemical Techniques, NMR, Mass Spectrometry in Structural and Molecular Recognition Studies', American Chemical Society 1994 short course *Frontiers in Organic Chemistry*, Stanford University, Palo Alto, CA.)

strength, the higher is the m/z range of the instrument. These instruments also require a very skilled operator and need a lot of maintenance. In a 1998 article, Alan Marshall stated, ''... more than 235 [Fourier transform ion cyclotron resonance mass spectrometry (FTICRMS) instruments] installations by 1998''.[120] In all likelihood, most of these instruments were installed within the past 5 years and are in use with ES interfaces for the analysis of proteins.

Over the 24 years since Marshall and Comisarow first published their findings, three companies commercially manufactured these instruments: Nicolet Instrument Corporation (Madison, WI), Bruker-Franzen Analytik GmbH (Bremen, Germany), and Ionspec Corporation (Irvine, CA). The lowest advertised price for an FTICR-MS in 1999 was approximately $350 000. Nicolet originally sold its patents and FTICR-MS business to Extrel (previously known as Extra Nuclear); Extrel was then acquired by Waters Corporation; Waters then sold the FTICR-MS business to Finnigan Corporation. Through all of these ownerships, instruments continued to be developed and manufactured in Madison, WI. In late 1998, Finnigan (ThermoQuest) closed all operations in Madison and began the development of a new FTICR-MS in their Bremen, Germany, factory. This new instrument has yet to be announced, leaving only Bruker and Ionspec as manufacturers of this system. The FTICR-MS began to gain a great deal of popularity for protein analyses by ES and MALDI. With the introduction of the TOF-MS and TOF hybrids, the FTICR-MS has lost some of its luster. The TOF instruments have sufficient resolving power to provide the needed information, and even at the high prices of the hybrid instruments are less costly than the FTICR-MS.

2.6.7 Tandem Mass Spectrometry

In his book *Introduction to Mass Spectrometry*, J. Throck Watson[7] states, ''From the stability standpoint there are roughly three types of ions produced in the [ion] source: (a) those that are stable for 100 μs or longer and thus reach the source intact, (b) those that decompose immediately (less than 10^{-7} s) after formation, and (c) those that decompose 1–100 μs after formation.'' Watson goes on to define these three ions as *stable*, *unstable*, and *metastable*, respectively. These metastable ions had been obscured in the earliest mass spectrometers of Thomson and Aston. The peaks produced by metastable ions on the photographically recorded mass spectrum were different from those produced by stable ions in that they were more diffuse. Thomson said these peaks were a result of 'secondary' rays and Aston called these peaks 'bands' in the mass spectrum.[33] The metastable ion (m^*) represents the precursor ion (m_1) and its resulting fragment (product ion, m_2) with the relation $m^* = (m_2)^2/m_1$. For a long time, these broad peaks in mass spectra interfered with the quantitation of individual compounds in hydrocarbon mixtures; therefore, the instruments were tuned to avoid their appearance. As time progressed, it became obvious that not only did these bands result from decomposition of ions labeled as metastable; but, most of the time, ion decomposition in a mass spectrometer resulted from high-energy collisions of stable ions with background gas molecules in the mass spectrometer, which led to Fred McLafferty coining the term 'CAD'.[104] [Graham Cooks coined the term 'collision-induced decomposition' (CID) in his 1978 book *Collision Spectroscopy* (Plenum, New York). Today, the CID abbreviation is used for collision-induced dissociation. Both CAD and CID are correct and are used interchangeably.]

In 1966, T.W. Shannon and McLafferty showed that by forcing decomposition of a stable ion, isomeric ions could be characterized.[121] McLafferty cites several other examples in the 'Introduction to Tandem Mass Spectrometry' chapter in *Tandem Mass Spectrometry*, an early and important reference to this technology.[104]

The acronym coined for the technique of bringing about a decomposition of a stable ion by a forced collision with neutral gas molecules was MS/MS. William F. Haddon defined the acronym as 'MS/MS' in a symposium organized by Michael L. Gross presented at the University of Nebraska (Lincoln, NE, November 3–5, 1976).[122] The term was later defined by McLafferty and Frank M. Bockhoff as 'mass separation/mass spectral characterization' by analogy to GC/MS.[123] However, MS/MS is the definition of MS/MS that is used today.

After the developments of CI and FD, it became obvious that in order to get structural information from low-energy ions representing the intact analyte molecule that were produced by soft ionization techniques, some method of ion fragmentation would be necessary. As the possibility of CAD became more of a reality, new instrumental methods would be required. Much of the early significance came out of the work by Graham Cooks and his colleagues at Purdue. The early work can be found in *Collision Spectroscopy*,[124] a 1978 book that Cooks edited, and his 1973 book *Metastable Ions*.[103] Cooks also published an *Analytical Chemistry* A-pages article in the January 1978 issue entitled 'Direct Analysis of Mixtures by Mass Spectrometry', which described the potential power of what would become known as MS/MS.[69] (Figure 27)

Two significant hardware developments were reported in the mid- to late-1970s that propelled the field of MS/MS: (1) the adaptation of conventional double-focusing mass spectrometers to have ions pass from an ion source into a magnetic sector, then through a collision cell, and finally through an electric sector, thus allowing for

Figure 27 Prior to the development of the triple-quadrupole mass spectrometer for MS/MS, the technique of mass analyzed ion kinetic energy spectrometry (MIKES) in double-focusing mass spectrometers was the technique used to obtain product-ion mass spectra of isolated ions from an initial ionization and/or fragmentation. Graham Cooks made the analogy of tandem MS/tandem spectroscopy as shown in this figure.[69]

the determination of the mass of the precursor ion and the product ion by Micky Barber and R.M. Elliot[125] in 1964; and (2) the development of the tandem-quadrupole mass spectrometer (the triple quadrupole) by Rick Yost and Chris Enke at Michigan State University (East Lansing, MI)[126] using technology originally described by D.C. McGilvery and J.D. Morrison at La Trobe University (Bundoora, Australia).[127] See Note 3 at the end of the article.

The about-to-be explosion of MS/MS was exemplified at the 1980 Pittsburgh Conference on Analytical Chemistry and Applied Spectroscopy (Atlantic City, NJ) with the introduction of three triple-quadrupole instruments (Finnigan Corporation, Extranuclear Laboratories, Inc., and SCIEX, Inc. – the TAGA 6000), a reverse-geometry double-focusing instrument by VG Micromass, Ltd. – the ZAB-2F (Cheshire, UK), and a triple-sector (electric–magnetic–electric) instrument custom-built for Mike Gross at the University of Nebraska with a price tag of $400 000–600 000.[128] Twenty years later, SCIEX (marketed through PE Biosystems), Finnigan (as part of ThermoQuest), and VG Micromass (with a triple-quadrupole instrument as opposed to its original reverse-geometry double-focusing instrument and as a subsidiary of waters) are all still strong producers of MS/MS instrumentation.

The 1980s was definitely the decade of the triple-quadrupole m/z analyzer. As the quadrupole ion trap developed as a mass spectrometer, its role in MS/MS was obvious. The QIT mass spectrometer began the era of tandem-in-time as opposed to tandem-in-space (Figure 28). The concept of tandem-in-time allows for multiple iterations of ion isolation and CAD fragmentation (MS^n). Although the quadrupole has helped to advance the technique of MS/MS, it is not a replacement for tandem-in-space, which still has an important role in the area of common-neutral-loss analysis and common product-ion scanning (Figure 29). Neither of these types of analyses are amenable for use with the tandem-in-time technique.

Figure 28 The concept of MS/MS as tandem MS in space vs tandem MS in time. (Adapted from J.V. Johnson, R.A. Yost, P.E. Kelly, D.C. Bradford, 'Tandem-in-space and Tandem-in-time Mass Spectrometry: Triple Quadrupoles and Quadrupole Ion Traps', *Anal. Chem.*, **62**, 2162–2172 (1992).)

2.7 Inorganic Mass Spectrometry

MS was originally used to determine the isotopes of the elements. It found some of its first applications in elemental analysis. The only preparative applications of MS have been in the area of purifying isotopes of elements. In recent years, MS has played a more publicized role in the analysis of organic compounds. However, like the solid analytical technique that it is, MS has advanced significantly in inorganic analyses. Surface analysis used to characterize papers used in laser printers and metal and composite skins of aircraft and materials put into outer space have advanced because of the continued development of SIMS. The ICP ion source for MS allows for the detection of trace elemental impurities in semiconductor manufacturing and the monitoring of inorganic pollutants in drinking and wastewaters.

2.7.1 Glow Discharge Mass Spectrometry

Glow discharge (GD) is the oldest ionization technique used in MS. John Aston gives a detailed account of his experiences with GD in the 1942 second edition of his book entitled *Mass Spectra and Isotopes*.[33] This technique was soon replaced by the spark-source technique in MS. In his 1965 book,[6] Robert Kiser states, ''The gaseous discharge ion source is largely of historical interest . . .''. John Roboz gives it about the same amount of space in his 1968 book.[10]

Although GD is best known as an ionization source for MS, it can be used in conjunction with other analytical techniques. GD has experienced a renaissance of interest in the last 20–30 years, largely due to the work of Willard W. Harrison at the University of Florida (Gainesville, FL). An *Analytical Chemistry* A-pages article by Harrison, 'GD Techniques in Analytical Chemistry', appeared in 1990 that described the use of GD with atomic absorption spectroscopy (AAS), atomic emission spectroscopy (AES), and atomic fluorescence spectroscopy (AFS) in addition to MS.[129]

One of the advantages that GD has over the other popular technique used for the analysis of inorganic samples (ICP) is that direct sampling of solids can be accomplished by GD. ICP requires that samples be in solution and nebulized or introduced as very fine aerosols. These aerosols can be produced from laser ablation or electrothermal vaporization. However, these intermediate sample techniques add to the cost and complexity of the method.

Another significant difference in these two inorganic MS techniques is the difference in the source pressure. The GD source operates at pressures similar to those used with CI in GC/MS, whereas the ICP source is an API source. A brief comparison of the operational parameters of the two techniques is described by Harrison.[130] This paper also includes additional references to other sources of comparison.

A search for articles in all ACS journals over the period 1996–1999 that contained 'GD' in their titles resulted in a list of 24. All but four of these were in *Analytical Chemistry*, and five were authored by Harrison. A similar search for articles containing 'ICP' resulted in a brief list of about a dozen articles related to MS. It does appear that GD as an ion source has had a higher degree of interest over the last few years; however, there are far more manufacturers of ICP mass spectrometers than there are of GD instruments. In his 1990 review of GD,[129] Harrison stated (without comment on the type of analyzer used) that commercial instruments were available from Extrel and VG Micromass. In all likelihood, the Extrel instrument was a TQ m/z analyzer and the VG Micromass instrument was based on a double-focusing sector instrument. In his 1999 paper, he states, ''Although most commercial GD MS instruments are coupled with double-focusing magnetic-sector units, the most recent developments in GD MS have been performed using quadrupole and TOF systems''.

Like ICP-MS, a common problem in glow discharge mass spectrometry (GD MS) is interferences from isobars of specific analytes due to polyatomic clusters of the analyte atoms and the analyte atoms with the inert gas (often Ar) used to create the plasma. A great deal of research has been conducted that has resulted in overcoming this problem in the ICP mass spectrometer, but has not been surmounted in the GD mass spectrometer. The ability to analyze solids is significant, but may not yield as much information or

the type of information that can be gained from SIMS. One of the reasons that ICP-MS dominates over GD MS is because much of the analytical MS involved with inorganic sample deals with analytes in solution.

2.7.2 Inductively Coupled Plasma Mass Spectrometry

In the 'Introduction' chapter to *ICP Spectrometry and its Applications*, Steve J. Hill, Editor (Sheffield Academic: Sheffield, UK; and CRC LLC, Boca Raton, FL, 1999), Stanley Greenfield and Michael Foulkes state that the first record of an ICP was made by J.J. Thomson in 1891.[131] Like GD, ICP is applicable to AAS, AES, and AFS in addition to MS.

Unlike GD, ICP did not become a mass technique until the mid-1970s, which was partly due to the requirement that the ICP be produced at atmospheric pressure. ICP had to wait until problems with API MS could be resolved. In 1974, Alan A. Gary, University of Surrey (Guild, Surrey, UK) published the use of a plasma jet as the ion source for a TQ mass spectrometer.[132] Gary continued to publish on this technique; however, in 1980 he took part in a feasibility study that changed his ion source to an ICP. The results of this study showed that elemental and isotopic compositions of solutions could be obtained with relatively little sample preparation.[133] This study was done with Robert S. Houk, who is at the US Department of Energy Ames Laboratory and the Department of Chemistry, Iowa State University (Ames, IA). Houk continues to be one of the leading researchers in ICP-MS.

Shortly after the Houk/Gary paper appeared, commercial instruments began to be introduced. The last half of the 1990s saw a number of new instruments and several significant technology advances. The 1997 and 1999 first-place *Analytical Instrument Industry (AII) Report* (Dr Gordon Wilkinson, Editor) Editors' and Writers' Award for the top three new instruments introduced went to instruments with ICP-MS technology advancements. The 1997 award went to Micromass (Manchester, UK) for the Platform-ICP (a TQ ICP mass spectrometer that used 'ICP-HEX-MS' to eliminate interferences from argon ions and reduce the energy dispersion of ions).[134] The 1999 award went to Perkin-Elmer (Wilton, CT) and MDS SCIEX (Concord, Ontario, Canada) for the ELAN 6100 DRC (dynamic reaction cell) ICP/MS system.[135] The PE/SCIEX DRC addressed the same problems as Micromass' ICP-HEX-MS, but used a different technology.[136]

Another significant advancement for ICP-MS was the introduction of a benchtop instrument by Hewlett-Packard (now Agilent Technologies) in 1997 through a joint venture with a Japanese developer. This product has been very successful and has brought ICP-MS within reach of many laboratories. Since 1994, every Pittsburgh Conference has seen the introduction of one or two new ICP-MS instruments. The ICP-MS technology is interfaced to double-focusing magnetic-sector TQ and TOF mass spectrometers. LECO Corporation (St. Joseph, MI) and GBC Scientific Equipment Pty. Ltd. (Dandenong, Victoria, Australia) introduced TOF-based ICP-MS instruments at the 1998 Pittsburgh Conference (New Orleans, LA). ICP-MS appears to have a good future in inorganic MS analyses.

2.7.3 Secondary Ion Mass Spectrometry

SIMS was an early development in MS. The study of surfaces by 'sputtering', although not thoroughly understood, was reviewed by H.S.W. Massey and E.S.H. Burhop in 1952.[137] They reported that in 1931 K.S. Woodcock at the Ryerson Physical Laboratory, University of Chicago (Chicago, IL), observed secondary-ion formation when a surface was bombarded with an ion beam.[138] According to Charles M. Judson,[139] Richard Herzog filed a German patent application for a SIMS instrument in 1942. In 1951, R.H. Plumlee reported on ion-sputtering techniques as being employed by RCA Laboratories (Princeton, NJ) for the analysis of solids in a symposium entitled 'Mass Spectroscopy in Physics Research' held September 6–9, 1951, at the NBS (now NIST).[140] R.E. Honig, also an employee of RCA Laboratories, is credited with much of the early work that proved productive in this field.[141,142]

SIMS involves the formation of ions on or near the surface by bombarding the sample with a beam of mass-selected ions. The resulting secondary ions are desorbed into the gas phase. This technique was used to study the impurities in material such as the aluminum used for airplane wings and germanium wafers used in early solid-state electrical devices. SIMS and its variants are widely used in the analysis and study of surfaces of all types of material – from papers used in laser printers, to microprocessor devices, to the wings of aircraft manufactured from many new polymeric composites.

As an interesting point, the abbreviation for SIMS is a pronounced acronym with an obvious 's' at the end, whereas the abbreviation for the technique used in chromatography/MS, selected ion monitoring (SIM), should not be used as an acronym because of the potential for confusion of these two entirely different techniques. Unfortunately, because of its ease of use, many people say '. . . analyzed by SIM' or '. . . a SIM analysis' rather than using the proper form '. . . analyzed by S-I-M' or '. . . an S-I-M analysis'. It is also proper to say each word when talking about either technique, but never use SIM as an acronym.

3 THE FUTURE OF MASS SPECTROMETRY

From its beginning with Thomson's 1897 report of the discovery of the electron (using what is considered

by many as the first mass spectrometer – the parabola mass spectrograph) to the present day status, the mass spectrometer has been and continues to be probably the most widely used analytical instrument. In all likelihood, MS technology has had the greatest impact on society of any analytical technique. Its nearest rival, nuclear magnetic resonance (NMR) spectroscopy, while enjoying a wide degree of use, has not had the impact of MS. The commercialization of and advances in (1) MALDI and ES instruments for the analysis of nonvolatile and thermally labile organics, (2) SIMS used in the characterization of organic and inorganic surfaces, (3) the specialty uses of MS such as RGAs that are used in space helmets to monitor patient health and medication performance, and in semiconductor manufacturing, (4) IR MS, and (5) ICP-MS have made MS a common technique for all fields of science.

The first 50 years were dominated by the physicists and their quest for the understanding of the ion optics of the magnetic-based single- and double-focusing instruments. As a result of MS's role in the development of the atomic bomb in World War II, the underlying principles of the sector-based mass spectrometer were well understood as we headed into the postwar years. The 1950s saw the embrace of the mass spectrometer by the organic chemist, the development of TOF technology, and the embryo of the quadrupole field by the physicist. The 1960s resulted in increased usage of MS by the organic chemist with the development of new ionization techniques such as CI and FD. The 1960s were also a period for the advances of MS instruments as RGAs and as a technique for the characterization of surfaces.

The 1970s were the decade of GC/MS and an entirely new paradigm for the analysis of complex mixtures of organic compounds. GC/MS led to new ways of looking at drinking and waste waters and drug metabolites, and for solving forensic puzzles, to name just a few of the new abilities. These analysis enhancements were possible because of the commercialization of the TQ, which radically changed the field of organic MS. Unfortunately, the 1970s also saw the beginning of the temporary decline of interest in the TOF mass spectrometer. The 1980s were the decade of MS/MS, and the 1990s were characterized by DI, which led to more developments in the area of LC/MS and the reemergence of the TOF mass spectrometer. During all three of these decades, uses of MS outside organic chemistry expanded, such as the popularity of ICP-MS using both the TQ and the double-focusing mass spectrometer.

As we move into the 21st century, MS takes on even more of a significance in science than it has had in the last decade. The MS literature is growing at a rapid rate with six English language journals devoted solely to the field. The ACS *Analytical Chemistry* journal is at least 25% MS, and Elsevier's *Journal of Chromatography A* and *Journal of Chromatography B* have as many articles related to the use of MS as they do to pure chromatographic techniques. By 1999, the extended abstracts, which comprised the proceedings of the ASMS annual meeting on MS and allied topics, had grown so large that it was no longer practical to publish a print edition. Therefore, after 38 years (the first time the meeting proceedings were published was 1961), ASMS discontinued publishing the proceedings of its meeting as a print issue and began sole distribution on CD-ROM.

Although yet to be established, it is possible that the next decade of MS will be the era of imaging. At the 1999 ASMS meeting (Dallas, TX), there were a number of reports on the use of MS to image the distributions of molecular-specific matter on the surfaces of materials such as contact lenses and in tissue slices from rat brain as well as polymeric surfaces that are used in composite aircraft wings.[143]

The advances that MS has made in (1) GC/MS and LC/MS, (2) surface analyses, inorganic analyses in environmental sciences and semiconductor manufacturing, to name only two, (3) residual gas analyses used in process monitoring and medicine, (4) detection of biological and chemical warfare agents, and (5) analyses of biopolymers with MALDI will continue at rates equal to those of the last three decades.

One thing is clear: In the first quarter of the 20th century, the inventions of Joe Thomson and John Aston in Manchester, UK, had as profound an effect on mankind as they did on the field of analytical chemistry.

4 EPILOG

It is important to remember that 'What you know about a subject is not nearly as significant as knowing where to find out what you need to know about that subject'. To that end, Appendix 1 of this article is a listing of important Web sites in 1999 that will help you locate much of the information you may need about MS. Appendix 2 is a bibliography of books on MS that have been published through 1999. Appendix 3 comprises a series of tables with helpful information that will be valuable in the interpretation of mass spectra of organic substances.

The MS section of this Encyclopedia contains articles that deal directly with techniques. In addition, there are articles that pertain to specific areas of analyses and analytes that also contain information on the use of MS. All of these articles, along with the referenced books in Appendix 2, will be invaluable in a concentrated study of any aspect of this exciting field of science.

ABBREVIATIONS AND ACRONYMS

AAS	Atomic Absorption Spectroscopy
ACS	American Chemical Society
AES	Atomic Emission Spectroscopy
AFS	Atomic Fluorescence Spectroscopy
APCI	Atmospheric Pressure Chemical Ionization
API	Atmospheric Pressure Ionization
ASMS	American Society for Mass Spectrometry
ASTM	American Society for Testing and Materials
CAD	Collisionally Activated Dissociation
CF-FAB	Continuous-flow Fast Atom Bombardment
CI	Chemical Ionization
CID	Collision-induced Dissociation
DC	Direct Current
DCI	Desorption Chemical Ionization
DEI	Desorption Electron Ionization
DI	Desorption/Ionization
DLI	Direct Liquid Introduction
DS	Data System
EI	Electron Ionization
EPA	United States Environmental Protection Agency
ES	Electrospray
FAB	Fast Atom Bombardment
FD	Field Desorption
FI	Field Ionization
FTICR	Fourier Transform Ion Cyclotron Resonance
FTICRMS	Fourier Transform Ion Cyclotron Resonance Mass Spectrometry
FTICR-MS	Fourier Transform Ion Cyclotron Resonance Mass Spectrometer
FTMS	Fourier Transform Mass Spectrometry
GC	Gas Chromatograph
GC/MS	Gas Chromatography/Mass Spectrometry
GC-MS	Gas Chromatograph–Mass Spectrometer
GD	Glow Discharge
GD MS	Glow Discharge Mass Spectrometry
HPLC	High-performance Liquid Chromatograph
ICP	Inductively Coupled Plasma
ICP-MS	Inductively Coupled Plasma Mass Spectrometer
ICR	Ion Cyclotron Resonance
ID	Inner Diameter
INCOS	Instrument Company Operating System
I^2QIT	Internal Ionization Quadrupole Ion-trap
IR	Infrared
IR MS	Isotope-ratio Mass Spectrometry
LC	Liquid Chromatograph
LC/MS	Liquid Chromatography/Mass Spectrometry
LC-MS	Liquid Chromatograph–Mass Spectrometer
LSIMS	Liquid Secondary Ion Mass Spectrometry
MALDI	Matrix-assisted Laser Desorption/Ionization
microES	Microelectrospray
MIKES	Mass Analyzed Ion Kinetic Energy Spectrometry
MS	Mass Spectrometry
MS/MS	Mass Spectrometry/Mass Spectrometry
nanoES	Nanoelectrospray
NBS	National Bureau of Standards
NIST	National Institute of Standards and Technology
NMR	Nuclear Magnetic Resonance
OEM	Original Equipment Manufacturer
PD	Plasma Desorption
PFTBA	Perfluorotributylamine
PONA	Paraffin, Olefin, Naphtha, and Aromatic
QIT	Quadrupole Ion-trap
RAM	Random Access Memory
RF	Radiofrequency
RGA	Residual Gas Analyzer
SIM	Selected Ion Monitoring
SIMS	Secondary Ion Mass Spectrometry
TOF	Time-of-flight
TOFMS	Time-of-flight Mass Spectrometry
TOF-MS	Time-of-flight Mass Spectrometer
TQ	Transmission-quadrupole
UV	Ultraviolet

NOTE

1. MS measures the abundance of ions according to their mass-to-charge ratios. Therefore, the abscissa of a mass spectrum is generally labeled with the units of mass-to-charge, not mass. The exception to this is the labeling of the abscissa of a mass spectrum constructed from the charge deconvolution of data with a series of multiple-charge ions. The units of mass are either unified atomic mass units with the symbol 'u' or daltons with the symbol 'Da'. The use of the symbol 'amu' for mass was discontinued in 1962.

   The amu symbol for a unit of mass was used when the standard for mass was based on oxygen-16. Physicists reported mass based on the most abundant naturally occurring stable isotope of oxygen [^{16}O, established by Francis William Aston (1877–1945) in 1929 after his discovery that oxygen was composed of three different isotopes, two of which had a higher mass (^{17}O and ^{18}O) than the most abundant isotope], which was assigned an exact mass of 16 (1 amu = 1/16 of the mass of ^{16}O). This definition was the basis of the *physical atomic mass scale*.

Chemists used amu to define a unit of mass as 1/16 the atomic weight (the average atomic mass) of oxygen [officially established in 1905 on the suggestion of the Belgian chemist Jean Servais Stas (1813–1891)]. This definition was the basis for the *chemical atomic mass scale*. The two scales differed by a factor of 1.000275 (physical > chemical).

An atomic weight is the weighted average of the masses of the naturally occurring stable isotopes of an element, and oxygen has three such isotopes. The atomic weight of oxygen was an absolute value of 16 by definition. The chemical atomic mass scale made the determination of the atomic weight of newly discovered elements easy by forming their oxides.

To eliminate the ambiguity between the physical and chemical standards, the standard of a single mass unit as 1/12 the most abundant naturally occurring stable isotope of carbon (^{12}C) was adopted in 1960 by the International Union of Physicists at Ottawa and in 1961 by the International Union of Chemists at Montreal. This standard is based on the independent recommendations of D.A. Olander and A.O. Nier in 1957. The symbol for the *unified atomic mass unit* was established as u, NOT μ, which appears in the *ASMS Guidelines* and in the 4th edition of *Interpretation of Mass Spectra* (McLafferty, 1993).

Prior to the oxygen standards, the basis for atomic mass had been set ca. 1805 by John Dalton (1766–1844) as 1 for the lightest element, hydrogen. In 1815, the Swedish scientist Jöns Jacob Berzelius (1779–1848), set the atomic weight (relative atomic mass) of oxygen to 100 in his table of atomic masses; however, the Berzelius standard of mass was not accepted. Stas's recommendation of setting the oxygen-16 standard allowed hydrogen to retain a mass close to 1, thereby keeping Dalton's scale somewhat intact.

2. When formed, ASMS had three vice-presidents: Programs, Arrangements, and Data & Standards. The vice-president of Data & Standards was not elected by the ASMS membership, but was the elected ASTM E-14 Committee Chair. In 1974, the ASMS membership changed the role of the E-14 Committee Chair to that of a non-elected Director-at-Large. The role of the E-14 Committee Chair in ASMS changed again in 1974 when the ASMS membership voted to no longer have a member of the E-14 as an automatic member of the ASMS Board of Directors. This position was replaced by a third Member-at-Large for Measurements and Standards to be elected by the ASMS membership. From that time forward, reports of E-14 meetings no longer appeared in the proceedings of the annual ASMS Conference on MS and Allied Topics. This change was made by ASMS because the interest of the ASMS membership was far broader than that of the E-14 Committee, and the interest of the E-14 Committee represented a small fraction of the diverse MS interest of ASMS. The year after the E-14 Committee Chair's removal from the ASMS Board of Directors, the ASTM abolished the official standing of the committee. Note: the above information is taken from reports of the annual meetings of ASMS from 1972 to 1998 as published in the Society's annual proceedings.
3. As the MS/MS technique developed, the term 'parent' was used to describe the precursor ion. The use of this word resulted in some confusion because organic mass spectrometrists had traditionally called the molecular ion a 'parent ion'. The product ion of a CAD was called the 'daughter ion'. The parent–daughter terminology led one group to coin the term DADI (pronounced daddy) as an acronym for direct analysis of daughter ions.[144] Today, this parent–daughter terminology is discouraged owing to its perceived offensive nature by some people. Therefore, the term DADI would no longer be appropriate.

APPENDIX 2: BIBLIOGRAPHY

(Reprinted with permission from O.D. Sparkman, *Mass Spectrometry Desk Reference*, Global View, Pittsburgh, PA, 2000)

Preparation of any such compilation is thwarted with the problem that by the time it reaches the intended audience, it will be out of date. Although this is the case with this current effort, the generation of this collection of book titles was, to some degree, inspired by two such collections that are found in books authored by Roboz in 1968 (reference 77) and Kiser in 1965 (reference 81). Both of these collections have proved to be invaluable in personal studies of MS. More recent collections of book titles in MS appeared in McLafferty and Tureček (Interpretation 6) and de Hoffman et al. (Introductory 8). Both of these collections, like the Roboz and Kiser collections, are dated, even though both were prepared in the 1990s.

The old adage, ''You can't judge a book by its cover!'' is truer today than ever before. Although there has been a number of outstanding MS books that address the new technologies developed at the end of the twentieth century, the literature of MS has been cursed with a plethora of recently published titles that suffer from bad technical content, little or no competent copyediting, and/or amateurish and sloppy production. These problems are due to consolidations in the publishing industry resulting in fewer publishers, a perceived need for new titles to replace older ones and to provide information on a subject that has exploded in the last decade with new ionization techniques, and the lack of desire and ability of authors to research their subject and avoid the self-gratification of generating an avalanche of neologisms and technical errors. These types of problems were practically nonexistent in books on MS before 1990.

There is a well-written and organized general text on MS (Introductory 4) that suffers from a less than adequate production effort. In this particular book, there is a lack of consistency in the fonts used for the presentation of reaction schemes, figures are improperly imported from electronic submissions, and promised graphics on the inside cover are replaced with an easy-to-lose insert. This book is the singularly best modern text on MS partially because its thousands of journal references all have titles. It is a shame that the publisher did not make the effort to do a better job of the presentation. This is one of the reasons why you see more self-publishing (Introductory 2 and Technique 10).

Another book, produced by a major publisher, consistently uses the word ''spectra'' (the plural form) for the word ''spectrum'' (the singular form) (Technique 6). As a corollary to ''you can't judge a book by its cover'', ''you can't necessarily judge a book by its title''. A book was published with the title *Understanding Mass Spectra – A Basic Approach* (Technique 3) when the title *Understanding Mass Spectra of Illicit Drugs* would have been more reflective of the contents and the complex spectra presented. There are also problems with poorly translated foreign-language books such as one originally written in French and translated into English by a person whose native language was Chinese (Introductory 8); reviewed in *J. Am. Soc. Mass Spectrom.*, **8**, 1193–1194 (1997). Another problem with translated books is the delay in information. By the time one of these books reaches its intended audience, the information is dated. This is especially true with the rapid change that is taking place in LC/MS and MS and biotechnology.

Most of the books on MS come from the chemists who use the technique. Chemistry, unlike biochemistry and the biological sciences, has been slow to recognize the importance of the titles of journal articles in cited references. Most of the MS books published in the last 10 years (and nearly all those previously published) do not include titles with cited journal articles. That is why a special effort has been made to mark books that do use titles in cited journal articles in this bibliography. These books are noted with an asterisk (*).

This bibliography is presented in 11 segments. Book-related segments include **Introductory**, **Reference**, **Technique-oriented**, **Interpretation**, **Historical Significance**, **Collections of Mass Spectra in Hardcopy**; and **Integrated Spectral Interpretation**. Non-book-related segments include **MS**; **GC/MS**; and **LC/MS Journals**; **Personal Computer MS Abstract Sources**; **Software**; and **Monographs**. These segments are included because of their importance in finding information on MS.

There is no inclusion of specific articles from journals. Through the 1960s, such listings of journal articles were published in various forms – often by MS instrumentation manufacturers. However, since the development of comprehensive abstracts systems and their electronic availability, these printed listings no longer have much value. The **Personal Computer MS Abstract Sources** section is a guide to information on current journal articles.

There is no inclusion of Internet search engines such as Medline and Chemical Abstracts Service. Some of these search engines are found on the **Important Worldwide Web URLs** in **Appendix 1**.

There has been some duplication of book titles. For example, the Watson book (Introductory 4 and Interpretation 4) covers two areas of MS. This book is excellent for the interpretation of EI spectra, as well as an introductory book. All books are listed in chronological order by section.

Introductory Books

The **Introductory Books** section contains titles of introductory books on MS, GC, and LC. If you are going to own only one MS book, it should be *Introduction to Mass Spectrometry*, 3rd edition (Introductory 4). This is a comprehensive book that touches on all the current technology. This book provides an excellent understanding of EI fragmentation mechanisms (which is essential to the understanding of all fragmentation in MS); and, of great importance, all of the journal articles referenced have titles. Another important book in this section is *Pushing Electrons: a Guide for Students of Organic Chemistry* (Introductory 3). This is a student workbook and instills a good understanding of moving electrons within organic ions and molecules, which is also essential to the understanding of mass spectral fragmentation.

MS Fundamentals (Introductory 9) is not a book. It is a multimedia training tool consisting of a computer-based training program, video, and book. This entry is also listed in the **Software** section. To those who work with the TQ mass spectrometer, this multimedia presentation is indispensable. In order to get the most from any analytical instrument, you must have a thorough understanding of the technology. This multimedia presentation will result in that understanding, even in those who have little technical background.

The **Introductory Books** section has three *Analytical Chemistry by Open Learning* titles (Introductory 1, 10, and 16). These books are programmed-learning texts and are very good for self-study. Two of the entries in this section are video courses produced by the ACS (Introductory 15 and 19). Neither is recommended because the MS course is dated, and the GC course has too little emphasis on capillary columns.

Reference Books

The citations in this section are meant to be general references on MS. In addition, there is a reference to LC method development. One of the most important entries in this section is the 'MS' article in the biennial Fundamental Reviews issue of *Analytical Chemistry*. This review began in 1949 with the article authored by John A. Hipple and Martin Shepherd (NBS, now the NIST) with 165 citations. The latest of these reviews (reference 5) had 1551 citations divided into nine categories: Overview (5), Scope (173), Innovative Techniques and Instrumentation (364), Isotope-ratio MS (89), High-power Lasers in MS (51), Dissociation by Low-intensity IR Radiation (18), Polymers (61), Peptides and Proteins (624), and Oligonucleotides and Nucleic Acids (166). The 'MS' articles in the Fundamental Reviews issues of *Analytical Chemistry* have had Alma L. Burlingame as their primary author since 1972 with 14 consecutive articles.

An important aspect of using a mass spectrometer is 'becoming one' with the instrument. In order to accomplish this, you must have an in-depth working understanding of the instrument. The multimedia training program distributed by SAVANT, *MS Fundamentals* (Introductory 9 and Software 23), is an excellent aid to gaining this understanding of the TQ mass spectrometer. In addition, the Dawson book (Reference 63) is a seminal reference for the TQ and the QIT. The March and Hughes book (Reference 35) is the seminal reference for the QIT, and the Cotter book (Reference 12) is a likewise reference for the TOF mass spectrometer. Care must be taken with respect to the Cotter title because he has edited a book (Reference 20) that does not provide the detailed understanding of TOFMS. The same is true for the March and Hughes book because of a similar title edited by March and Todd (Reference 17). There is no good reference for the current technology of magnetic-sector mass spectrometers. The best material on understanding the fundamentals of a magnetic-sector and/or double-focusing instrument is the Roboz book (Reference 77). The best understanding of the workings of FTMS is found in an article, 'Fourier Transform Ion Cyclotron Resonance Mass Spectrometry: A Primer', authored by Allen Marshall et al. in *Mass Spectrom. Rev.*, **17**(1), 1–36 (1998).

Working with mass spectrometers often requires the derivatization of analytes to obtain the best results. This section has three good books that aid in this task (References 25, 53, and 78). In addition, there are two other books that do not primarily pertain to MS techniques: *Basic Vacuum Practice* from Varian (Reference 36) and *The Mass Spec Handbook of Service* by Manura (Reference 24).

It should be noted that several books of the 1960s and early 1970s have been reprinted in the past few years (References 63, 82, and 84) by the American Institute of Physics and the ASMS. This is not a new practice. Several titles were reprinted by a publisher other than the original publisher several years after the first printing. ASMS plans to reprint several other titles of both historical and technological significance over the next few years.

1. *S.J. Hill (ed.), *ICP Spectrometry and its Applications*, Sheffield Academic, Sheffield, 1999.
2. K.W. Shepard (ed.), *Heavy Ion Accelerator Technology*, Eighth International Conference (AIP Conference Proceedings), American Institute of Physics, New York, Vol. 473, 1999.
3. *O.D. Sparkman, (p. 2604), G.J. Wells, C.K. Huston, (p. 2662), F. Adams et al., (p. 2650), in *Encyclopedia of Environmental Analysis and Remediation*, ed. R.A. Meyers, Wiley, New York, Vol. 4, 1998.
4. E.J. Karjalainen, A.E. Hesso, J.E. Jalonen, U.P. Karjalainen (eds.), *Advances in Mass Spectrometry*, Proceedings of the 14th International Conference, 1997, Tampere, Finland, Elsevier, Amsterdam, 1998 (also available as a CD ROM).
5. A.L. Burlingame, R.K. Boyd, S.J. Gaskell, 'Mass Spectrometry', in the Fundamental Reviews issue of *Anal. Chem.*, **70**(16), (1998).
6. C. Tuniz, J.R. Tuniz, D. Fink Bird (eds.), *Accelerator Mass Spectrometry: Ultrasensitive Analysis for Global Science*, CRC Press, Boca Raton, FL, 1998.
7. H.E. Grove, *From Hiroshima to the Iceman: the Development and Applications of Accelerator Mass Spectrometry*, American Institute of Physics, New York, 1998.
8. A. Montaser (ed.), *Inductively Coupled Plasma Mass Spectrometry*, VCH, Berlin, 1998.
9. L.T. Platzner, K. Habfast, A. Walder, A. Goetz, *Modern Isotope Ratio Mass Spectrometry*, Wiley, New York, 1997.
10. G. Holland, S.D. Tanner (eds.), *Plasma Source Mass Spectrometry: Development and Applications*, International Conference on Plasma Source Mass Spectrometry, American Chemical Society, Washington, DC, 1997.
11. C.L. Wilkins, 'Mass Spectrometry', in *Handbook of Instrumental Techniques for Analytical Chemistry*, ed. F.A. Settle, Prentice Hall, Upper Saddle River, NJ, Section V, 1997.
12. R.J. Cotter, *Time-of-flight Mass Spectrometry: Instrumentation and Applications in Biological Research*, American Chemical Society, Washington, DC, 1997.
13. L.R. Snyder, J.J. Kirkland, J.L. Glajch, *Practical HPLC Method Development*, 2nd edition, Wiley, New York, 1997.

14. A.E. Ashcroft, *Ionization Methods in Organic Mass Spectrometry*, RSC Analytical Spectroscopy Monographs, Royal Society of Chemistry, Cambridge, 1997.
15. T. Baer, C.-Y. Ng, I. Powis (eds.), *Large Ions: Their Vaporization, Detection and Structural Analysis*, Wiley, New York, 1996.
16. A. Townsend et al. (ed.), *Encyclopedia of Analytical Science*, Academic Press, San Diego, CA, 1995.
17. R.E. March, J.F.J. Todd (eds.), *Practical Aspects of Ion Trap Mass Spectrometry*, CRC Press, Boca Raton, FL, Vols. I–III, 1995.
18. P.K. Ghosh, *International Series of Monographs on Physics, 90: Ion Traps*, Oxford Science, New York, 1995.
19. I. Corndies, G.y. Horváth, K. Vékey (eds.), *Advances in Mass Spectrometry*, Proceedings of the 13th International Conference, 1995, Budapest, Elsevier, Amsterdam, 1995.
20. R.J. Cotter (ed.), *Time-of-flight Mass Spectrometry*, ACS Symposium Series 549, American Chemical Society, Washington, DC, 1994.
21. E.W. Schlag (ed.), *Time-of-flight Mass Spectrometry and its Applications*, Elsevier, Amsterdam, 1994.

Technique-oriented Books

The books listed in this section pertain to specific techniques of MS and hyphenated chromatography/MS techniques. In some cases, the books are specific to certain types of analytes. Books of this type began to appear at the end of the 1960s (only one listing before 1970, Technique 91). Slightly more than half of these books (47 out of 90) have copyright dates in the last decade. Unfortunately, the last three or four years have seen a proliferation of very poorly written books with little or no copyediting and poor quality production.

One of the titles in this section (Technique 6), as well as one in the **Interpretation Books** section (Interpretation 3), is not of much merit. The *JASMS* reviews of both these books expressed an opinion that they would be more harmful to the reader than helpful [Technique 6: *J. Am. Soc. Mass Spectrom.*, **10**, 364–367 (1999); Interpretation 3: *J. Am. Soc. Mass Spectrom.*, **9**, 852–854 (1998)].

Many of the technique-oriented books are made obsolete by changing technology within a few years or months of their publication. A good example is the 1990 Yergey book (Technique 39) on LC/MS. Because of the massive advancements in technology that have taken place in the last 10 years, this book had little relevance to

the technique within 2 years of its publication. The book still has a great deal of value in that it provides good information on how to perform the chromatographic separations required in LC/MS, and it has an excellent set of journal-article references that contain titles. The problem of dated material can be especially significant with foreign-language books that are translated into English. Unfortunately, in some cases, publishers do not indicate that a book has been translated. It is only through careful research that the foreign-language routes of a book can be established. This is the case with Technique 2.

There are two books (Techniques 10 and 21) that are of particular value to the LC/MS and GC/MS practitioner, respectively. These two books have a great deal of practical information on the running of different types of analyses and are good aids in the decision-making process about how to proceed with a particular sample. The Willoughby book (Technique 10) has very useful information in deciding whether to use a contract laboratory or perform the analysis in-house. The Willoughby book was reviewed in *J. Am. Soc. Mass Spectrom.*, **10**, 78–79 (1999), as was the Kitson book, *J. Am. Soc. Mass Spectrom.*, **9**, 294–295 (1997). Care must be taken with respect to the unfortunate similarity between the titles of the Kitson book (Technique 21) and that of Technique 6.

Books that are edited works rather than having a single author generally do not get my approval. These edited editions often end up looking like a 'camel' (a horse designed by a committee). This is more true of books published in the last two decades than those published before that time. There is one notable exception in Technique 16 by Cole, reviewed in *J. Am. Soc. Mass Spectrom.*, **8**, 1191–1192 (1997). This book is an excellent reference for those working in ES. The second edition of the Niessen book (Technique 5) is also a good reference for ES and also other LC/MS techniques. The single negative aspect of both of these books is that they do not include titles with journal citations.

There are two important references on environmental GC/MS that should be reviewed by anyone working in this area (Techniques 71 and 73). Although both of these books were written in the era of the packed column, the fundamentals of environmental analyses and the United States Environmental Protection Agency (EPA) tune criteria are covered in detail.

Another reference of the packed-column era is the McFadden book (Technique 86). This book, along with the Karasek book (Introductory 18), is very useful to those starting in GC/MS.

If you are using CI (either APCI or CI under the conditions normally encountered in GC/MS), you need the Harrison book (Technique 33). Unlike the Yinon book (Technique 27), this book is a second edition and is labeled as such.

In looking at new titles of technique-orientated books, care must be taken to know when the title is nothing more than the collection of a series of articles from a journal or a bound issue of a journal. The value of such books is often less than their extremely high selling price.

Interpretation Books

The seminal book for the interpretation of EI mass spectra is the McLafferty book (Interpretation 6). This book is extremely valuable, but may be too advanced for a beginner trying to self-teach. The beginner should try to start with either the McLafferty 2nd edition book (Interpretation 8) or the book by Shrader (Interpretation 1), both of which have been out of print for some time but can be found on the used-book Web sites.

The books by Budzikiewicz et al. (Interpretations 19, 23, and 24) were the first books written using mechanisms in organic reactions to describe the fragmentation of energetic ions produced by EI. The information in these books still has a great deal of relevance to the subject. All of the interpretation books listed in this section pertain primarily to odd-electron molecular ions formed by the EI process. The ions formed in LC/MS are predominately protonated molecules, which are even-electron ions. Even-electron ions fragment to produce other even-electron ions, which requires the breaking of more than one bond in the ion. Many of the neutral losses in even-electron ion fragmentation and odd-electron ion fragmentation are the same.

One important note on Interpretation 3: just as book titles can be similar (Techniques 6 and 22), people can have the same or similar names that can result in confusion. The author of Interpretation 3, Terrence A. Lee, a Department of Chemistry faculty member at Middle Tennessee State University in Murfreesboro, TN, should not be confused with Terry Lee, a noted researcher in MS of biological substances at the Beckman Research Institute, City of Hope/Division of Immunology in Duarte, CA.

Books of Historical Significance

* Note that historical references are in the Bibliography section of the Kiser book (Reference 81) and in the Information and Data chapter of the Roboz book (Reference 77).

Based on an 1886 paper [*Berl. Ber.*, **39**, 691 (1886)] by Eugene Goldstein (German physicist, 1850–1930) reporting the discovery of luminous rays emerging as straight lines from holes in a metal disc used as a cathode in a discharge tube (he called the rays Kanalstrahlen – canal rays) and the confirmation by Wilhelm Carl Werner Otto Fritz Franz Wien (German Nobel Laureate in Physics, 1911; 1864–1928) that Jean Baptiste Perrin's (French physicist, 1870–1942) 1895 postulation that the rays were associated with positive charge by studying their deflection in electric and magnetic fields [*Verh. Phys. Ges.*, **17**, 1898 (1898); *Ann. Phys.*, **65**, 440 (1898); *Ann. Phys. Leipzig*, **8**, 224 (1902)], the field of MS developed into a science between 1911 and 1925. This was due to the results of the experiments conducted by the three founding fathers of MS: Joseph John Thomson (English Nobel Laureate in Physics, 1906; 1856–1940); Francis William Aston (English Nobel Laureate in Chemistry, 1922; 1877–1945; Aston was an associate of Thomson in the Cavendish Laboratory in Manchester, England); and Arthur Jeffery Dempster (1886–1950, Canadian–American physics professor, University of Chicago).

In his 1968 book, Roboz (Reference 77) lists 20 selected papers for those wanting to learn the history of MS through original references (Chapter 14, page 490). Of these papers, five were authored by Aston, four by Dempster, and two by Thomson. Another three were authored by William R. Smythe (US scientist) and two by Kenneth Bainbridge (US physicist, 1904–1906, Director of the Trinity test – the first test explosion of the atomic bomb), who also were early pioneers in MS.

Collections of Mass Spectra in Hard Copy

There have been many collections of mass spectra that have come and gone. In a 1985 monograph (*A Guide to, and Commentary on, the Published Collection and Literature of Mass Spectral Data*) published by VG Analytical (the UK MS company now known as Micromass/Waters), 33 separate collections were referenced. In 1974 and 1978, the ASMS published the 1st and 2nd editions of *A Guide to Collections of Mass Spectral Data*. These editions include 24 and 30 references, respectively. None of these collections has been lost. They have all been consolidated into either the NIST98 Mass Spectral Database or the Wiley Registry of Mass Spectral Data, or both. Some of these collections are not currently available in an electronic format, or the electronic format is only of abbreviated spectra that range from a minimum of 16 to a maximum of 50 mass spectral peaks (Collections 6). Hard-copy volumes are somewhat less valuable than electronic versions. The Cornu collection is even less valuable because it is a tabular listing of the 10 most intense peaks.

Mass Spectrometry, Gas Chromatography/Mass Spectrometry, and Liquid Chromatography/Mass Spectrometry Journals

Articles containing information on MS can be found in many different scientific journals in addition to those listed below. This is a listing of journals that are specific to MS (Journals 1, 2, 3, 4, 5, 6, 8, 9, 15, and 16), that pertain to a specific analytical technique (Journals 10 and 11), or that pertain to general chemistry (Journals 7, 12, 13, and 14). Some of the journals have complimentary subscriptions (Journals 12, 13, and 14), whereas other journals have annual subscription rates of thousands of dollars (Journals 1, 4, 6, 10, and 11). Some journals have reasonable society membership rates (Journals 2 and 7). The more expensive journals often have reasonable individual subscription prices (Journals 1 and 4).

In addition to review and research articles, most of these journals also provide reviews of software, books, and other items of interest to the mass spectrometrist. The exceptions are the proceedings of meetings (Journals 16 and 17) and list and/or abstract sources (Journals 8 and 9).

One of the interesting features of *Journal of Mass Spectrometry* (Journals 1) is a section entitled 'Current Literature in MS' that appears at the end of every issue. This is a bibliography of articles published over the past 6–8 weeks. It is divided into 11 major sections with the Biology/Biochemistry section subdivided into four additional categories. At the end of each volume, all the listings for the year are made available in a Microsoft® Access format that can be searched electronically.

1. *Journal of Mass Spectrometry*, Wiley, Chichester (formerly *Organic Mass Spectrometry*, incorporating *Biomedical Mass Spectrometry*).
2. *Journal of the American Society for Mass Spectrometry*, Elsevier, New York.
3. *European Mass Spectrometry*, IM Publications, Chichester.
4. *Rapid Communications in Mass Spectrometry*, Wiley, Chichester.
5. *Mass Spectrometry Reviews*, Wiley, New York.
6. *International Journal of Mass Spectrometry and Ion Processes*, Elsevier, New York.
7. *Analytical Chemistry*, American Chemical Society, Washington, DC.
8. *CA Selects Plus: Mass Spectrometry*, American Chemical Society, Washington, DC.
9. *Mass Spectrometry Bulletin*, Royal Society of Chemistry, Cambridge.
10. *Journal of Chromatography A*, Elsevier, Amsterdam.
11. *Journal of Chromatography B*, Elsevier, Amsterdam.
12. *American Laboratory*, ISC, Shelton, CT.
13. *LC/GC*, Advanstar, Eugene, OR.
14. *Spectroscopy*, Advanstar, Eugene, OR.
15. *Proceedings of the nth ASMS Conference on Mass Spectrometry and Allied Topics*, published annually, American Society for Mass Spectrometry, Santa Fe, NM (ASTM E14 Committee Meetings began in 1952 – published annually from 1961 to 1969, ASTM E14 Committee Meeting Proceedings – ASMS began in 1970 with the 18th Conference Proceedings).
16. *Advances in Mass Spectrometry*, Proceedings of the Triennial International Mass Spectrometry Conference. Vols. 1, 2, and 3 (1958, 1961, and 1964) can be found in the **Books of Historical Significance** section and Vols. 12, 13, and 14 (1991, 1994, and 1997) in the **Reference Books** section of this bibliography. There are Vols. 4–11 for meeting years 1967, 1970, 1973, 1976, 1979, 1982, 1985, and 1988. The first six meetings were held in the UK. Beginning with the 7th meeting (Florence, Italy), each succeeding meeting has been held in a different European country. The next meeting is scheduled for Barcelona, Spain, in 2000.

Monographs

All the citations in this section are from VG Instruments/Micromass. All instrument manufacturers publish application notes; however, Micromass (and its preceding companies) is the only manufacturer that has published this type of general-topic monograph. These monographs are like review articles found in *Mass Spectrometry Reviews* or the Special Features section of the *Journal of Mass Spectrometry*. These monographs are not as well referenced as the articles in the two journals mentioned, but do provide a good overview of the subject. Such promotional material is of benefit to those wanting to get a quick understanding of a topic, and it is hoped that more of this type of material will be forthcoming.

Another example of the ready-reference-material approach to information dissemination is found in the Siuzdak book (Introductory 6). This book was written to provide a quick understanding of MS to biotechnology executives who have to make financial decisions about MS instrumentation and facilities.

Integrated Spectral Interpretation Books

General integrated spectral interpretation books include information on the interpretation of proton NMR, IR, and mass spectra, as well as how to use UV data in conjunction with the previous three spectral techniques. Some books also include a section on ^{13}C-NMR. These books are good for an overview of the subject, but do not provide the in-depth MS interpretational information.

In addition to the books listed below, the Mathieson book (Interpretation 22) is also an integrated book in that it includes separate sections on NMR and IR, in addition to the one on MS.

Software

There are several programs that are available as self-training. Those programs developed by the UK company

Cognitive Solutions (Software 10–13) are somewhat like English roast beef. They are intellectually nutritious; however, they fail to excite the experiential palate. Equivalent titles available from SAVANT (Software 14–22) will hold the user's interest in a much more conductive manner for learning. Just as the *MS Fundamentals* program is a seminal tool in the development of the understanding of the TQ mass spectrometer, *Fundamentals of GC/MS* is one of the better instrument-user software packages developed. This program was initially developed and sent out several times for review to a number of people who are involved in training on various aspects of GC/MS and in the development of training programs. The result is what is assured to become an award-winning effort.

All of the training programs from SAVANT and Cognitive Solutions were developed in Interactive ToolBook, a powerful tool for the development of training programs. All have tests built into the programs to allow the user to evaluate the results of the training.

The two volumes of *SpectraBook* are also based on the Interactive ToolBook platform. These two programs each contain data on 50 separate compounds: mass, proton NMR, ^{13}C-NMR and IR spectra as well as the structure, molecular weight based on the atomic weights of each compound's elements, physical properties, and several synonyms. Help files are provided to assist the user in developing desired interpretational skills. Another nice feature is the ability to display what properties result in specific spectral peaks. Placing the mouse pointed on a labeled mass spectral peak and holding down the left mouse button will result in a display of the mechanism(s) that produced the ion represented by that peak. Similar displays are provided for the other types of spectra.

It is unfortunate that the author of *SpectraBook* (programs copyrighted in 1990 and 1992) did not take more care to be correct in some of the presentations such as the use of *m*/*z* as the symbol for mass-to-charge (inappropriately written Mass to Charge on the abscissa of mass spectra) ratio instead of the *m*/*e* symbol, which was replaced in the 1970s. The indicated shift of pairs of electrons in the displayed mechanism for beta cleavage resulting from a gamma-hydrogen shift does not instill confidence in the accuracy of instruction.

The programs published by ChemSW (Software 1–9) are very well thought out and provide utilities that are not found in the data-system software for most, if not all, commercially available instruments. The titles of these programs are self-explanatory.

The two programs associated with the Wiley and NIST Mass Spectral Databases (Software 31 and 33) are widely available from a number of different sources. A number of GC/MS and LC/MS programs now provide the NIST Mass Spectral Search Program as the search routine used with their proprietary instrument software. Both of the programs are capable of reading most, if not all, commercially available instrument data formats.

Table 1 Element/isotopic mass and abundance data

Type	Element	Symbol	Integer mass[a]	Exact mass[b]	Percent abundance	$X+1$ factor[c]	$X+2$ factor[d]
X	Hydrogen	H	1	1.0078	99.99		
		D or ^{2}H	2	2.0141	0.01		
$X+1$	Carbon	^{12}C	12	12.0000	98.91		
		^{13}C	13	13.0034	1.1	$1.1n_{C}$	$0.0060n_{C}^{2}$
$X+1$	Nitrogen	^{14}N	14	14.0031	99.6		
		^{15}N	15	15.0001	0.4	$0.37n_{N}$	
$X+2$	Oxygen	^{16}O	16	15.9949	99.76		
		^{17}O	17	16.9991	0.04	$0.04n_{O}$	
		^{18}O	18	17.9992	0.20		$0.20n_{O}$
X	Fluorine	F	19	18.9984	100		
$X+2$	Silicon	^{28}Si	28	27.9769	92.2		
		^{29}Si	29	28.9765	4.7	$5.1n_{Si}$	
		^{30}Si	30	29.9738	3.1		$3.4n_{Si}$
X	Phosphorus	P	31	30.9738	100		
$X+2$	Sulfur	^{32}S	32	31.9721	95.02		
		^{33}S	33	32.9715	0.76	$0.8n_{S}$	
		^{34}S	34	33.9679	4.22		$4.4n_{S}$
$X+2$	Chlorine	^{35}Cl	35	34.9689	75.77		
		^{37}Cl	37	36.9659	24.23		$32.5n_{Cl}$
$X+2$	Bromine	^{79}Br	79	78.9183	50.5		
		^{81}Br	81	80.9163	49.5		$98.0n_{Br}$
X	Iodine	I	127	126.9045	100		

[a] The integer mass of the most abundant[e] naturally occurring stable isotope of an element is the element's *nominal mass*. The nominal mass of an ion is the sum of the nominal masses of the elements in its empirical formula (e.g. $C_3H_6O^{+\bullet}$ has a nominal mass of 58).
[b] The exact mass of the most abundant[e] naturally occurring stable isotope of an element is the element's *monoisotopic mass*. The monoisotopic mass of an ion is the sum of the monoisotopic masses of the elements in its empirical formula (e.g. $C_3H_6O^{+\bullet}$ has a monoisotopic mass of 58.0417).
[c] Assume $X = 100\%$; X represents the relative intensity of the first peak in a cluster of peaks corresponding to isotopic variants of a given ion.
[d] The factor is multiplied by the number (n) of atoms of the element present to determine the magnitude of the intensity contribution for a given isotope. For example, the contribution at $X+1$ due to ^{15}N for an ion containing three nitrogens would be $0.37 \times 3 = 1.11$ relative to 100 at X.
[e] This may not always be the lowest mass naturally occurring stable isotope of the element, as is the case with the elements in this table. The lowest mass isotope of Hg is 196 and the nominal mass isotope is 202, seventh from the lowest mass isotope.

APPENDIX 3: MASS SPECTRAL INTERPRETATION DATA

EI fragmentation data are given in Tables 1 and 2, Figures 30 and 31, and Tables 3 and 4.

Proof of a Molecular Ion Peak – $M^{+\bullet}$

1. If a compound is known, the molecular ion has a mass-to-charge ratio (m/z) value equal to the sum of the atomic masses of the most abundant isotope of

Table 2 Common fragment ion

29	HCO^+	Aldehydes
30	$CH_2NH_2^+$	Amines
31	$H_2C{=}\overset{+}{O}H$	Alcohols
	CH_3O^+	Methyl esters
43	$C_3H_7^+$	Propyl ion
	CH_3CO^+	Acetyl groups
47	CH_3S^+	Sulfides
49	CH_2Cl^+	Chloro compounds
55	$C_4H_7^+$	Alkyl groups
57	$C_4H_9^+$	Alkyl groups
	$C_2H_5CO^+$	Acylium ion
58	$(H_2C\overset{H}{\diagup}COCH_3)^{+\bullet}$	Ketones with a γ-hydrogen
59	$(COOCH_3)^+$	Methyl esters
61	$CH_3\overset{OH}{C}{=}O^+H$	Esters of high molecular weight alcohols
70		Pyrrolidines
74	$(CH_2{=}\overset{OH}{C}{-}OCH_3)^{+\bullet}$	Methyl esters with a γ-hydrogen
77	$C_6H_5^+$	Aromatics
78	$C_5H_4N^+$	Pyridines and alkyl pyrroles
80		Pyrroles
80 (82)	$HBr^{+\bullet}$	Bromo compounds
81		Furans
		Aliphatic chain with two double bonds
83	$C_6H_{11}^+$	Cyclohexanes or hexenes
	$CHCl_2^+$	Chloro compounds
85		Tetrahydropyranyl ethers
88	$CH_3OCO{=}CH$ $\overset{+}{N}H_2$	Amino acid esters
91	$C_7H_7^+$	Aromatic hydrocarbons with side chains
92	$C_7H_8^+$	Benzyl compounds with a γ-hydrogen
95		Furyl−CO−X
97		Alkyl thiophenes
99		Ethylene ketals of cyclic compounds (steroids)
104	$C_8H_8^{+\bullet}$	Alkyl aromatics
105	$C_6H_5CO^+$	Benzoyl compounds
	$C_8H_9^+$	Aromatic hydrocarbons
106	$CH_2{=}\overset{+}{N}H_2$	Amino benzyl
107	$C_7H_7O^+$	Phenolic hydrocarbons
117	$C_9H_9^+$	Styrenes
128	HI^+	Iodo compounds
130		Indoles
131		Cinnamates
149		Dialkyl phthalates (rearrangement)

Figure 30 Fragments produced by the EI of perfluorotributylamine (PFTBA) that are used for the calibration of the mass spectrometer's m/z scale. The molecular weight of PFTBA (FC-43), used to calibrate the m/z scale of TQ and QIT mass spectrometers operated in the EI mode, is 671. The following is an explanation of the origin of some of the peaks observed in its EI mass spectrum:

$$\begin{array}{lll} 671 & 671 & 671 \\ -207 & -507 & -57 \\ \hline 464 & 164 & 614 \\ & & 169 \\ -50 & +100 & -38 \\ \hline 414 & 264 & 131 \end{array} \quad \begin{array}{l} (3\times 69) \\ \\ (2\times 19) \end{array} \quad \begin{array}{l} (3\times 169) \\ \\ \\ \end{array} \quad \begin{array}{l} (3\times 19) \\ \\ (2\times 19) \end{array}$$

Table 3 Chlorine and bromine isotopic abundance ratios

Atoms of ClBr	X	$X+2$	$X+4$	$X+6$	$X+8$	$X+10$
Cl	100	32.5				
Cl_2	100	65.0	10.6			
Cl_3	100	97.5	31.7	3.4		
Cl_4	76.9	100	48.7	0.5	0.9	
Cl_5	61.5	100	65.0	21.1	3.4	0.2
Cl_6	51.2	100	81.2	35.2	8.5	1.1
ClBr	76.6	100	24.4			
Cl_2Br	61.4	100	45.6	6.6		
Cl_3Br	51.2	100	65.0	17.6	1.7	
$ClBr_2$	43.8	100	69.9	13.7		
Cl_2Br_2	38.3	100	89.7	31.9	3.9	
Cl_3Br_2	31.3	92.0	100	49.9	11.6	1.0
$ClBr_3$	26.1	85.1	100	48.9	8.0	
Cl_2Br_3	20.4	73.3	100	63.8	18.7	2.0
Br	100	98.0				
Br_2	51.0	100	49.0			
Br_3	34.0	100	98.0	32.0		
Br_4	17.4	68.0	100	65.3	16.0	

each element that comprises the molecule (assuming the ion is a single-charge ion).

2. The nominal molecular weight of a compound, or the m/z value for the molecular ion, is an even number for any compound containing only C, H, O, S, Si, P, and the halogens.

   Fragment ions derived via homolytic, heterolytic, or sigma-bond cleavage from these molecular ions (even m/z) have an odd m/z value and an even number of electrons.

Figure 31 Graphical representation of relative isotope peak intensities for any given ion containing the indicated number of chlorine and/or bromine atoms. Numeric values are shown in Table 3. Steps to determine elemental composition based on isotope peak ratios:

1. Determine the nominal m/z value peak (peak at lowest m/z value, above which other peaks can be attributed to isotopic multiplicity or background).
2. Assign the $X+2$ elements, except oxygen.
3. Assign the $X+1$ elements. (Remember to normalize $X+1$ to X, if necessary.)
4. Balance the mass.
5. Assign the atoms of oxygen.
6. Balance the mass.
7. Assign the X elements.
8. From the empirical formula, determine the number of rings plus double bonds.
9. Propose a possible structure.
10. Does it make sense?

Fragment ions derived from these molecular ions (even m/z) via expulsion of neutral components (e.g. H_2O, CO, ethylene) have an even m/z value and an odd number of electrons.

3. *Nitrogen rule*: a compound containing an odd number of nitrogen atoms – in addition to C, H, O, S, Si, P, and the halogens – has an odd molecular weight.

   Molecular ions of these compounds fragment via homolytic, heterolytic, or sigma-bond cleavage to produce ions of an even m/z value unless the nitrogen atom is lost with the neutral radical.

Table 4 Common neutral losses

M – 1	Loss of hydrogen radical	M – $^{\bullet}H$
M – 15	Loss of methyl radical	M – $^{\bullet}CH_3$
M – 29	Loss of ethyl radical	M – $^{\bullet}CH_2CH_3$
M – 31	Loss of methoxyl radical	M – $^{\bullet}OCH_3$
M – 43	Loss of propyl	M – $^{\bullet}CH_2CH_2CH_3$
M – 45	Loss of ethoxyl	M – $^{\bullet}OCH_2CH_3$
M – 57	Loss of butyl radical	M – $^{\bullet}CH_2CH_2CH_2CH_3$
M – 2	Loss of hydrogen	M – H_2
M – 18	Loss of water	M – H_2O
M – 28	Loss of CO or ethylene	M – CO or M – C_2H_4
M – 32	Loss of methanol	M – CH_3OH
M – 44	Loss of CO_2	M – CO_2
M – 60	Loss of acetic acid	M – CH_3CO_2H
M – 90	Loss of silanol: $HOSi(CH_3)_3$	M – $HOSi(CH_3)_3$

An even number of nitrogen atoms in a compound results in an even nominal molecular weight.

4. The molecular ion peak must be the highest m/z value of any significant (nonisotope or nonbackground) peak in the spectrum. Corollary: the highest m/z value peak observed in the mass spectrum need not represent a molecular ion.
5. The peak at the next lowest m/z value in the mass spectrum must not correspond to the loss of an impossible or improbable combination of atoms.
6. No fragment ion may contain a larger number of atoms of any particular element than the molecular ion.

Courses on the interpretation of mass spectra and techniques of MS are offered by the Continuing Education Department of the ACS: http://www.acs.org/education/profdevl/short.html.
